Evolve® Online Courseware for **Bonagura/Twedt: Current Veterinary Therapy XIV**, offers the following features:

Resources

- Selected chapters from *CVT XIII*
- Fully searchable index
- Drug formulary
- References linked to Pub Med
- Other helpful appendices
- Image collection

KIRK'S --- CURRENT VETERINARY THERAPY XIV

Editor

John D. Bonagura, DVM, MS, DACVIM
(Cardiology, Internal Medicine)
Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio

Associate Editor

David C. Twedt, DVM, DACVIM
(Internal Medicine)
Professor
Department of Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

SECTION I CRITICAL CARE

Nishi Dhupa, BVM, DACVIM (Internal Medicine), DACVECC

SECTION II TOXICOLOGIC DISEASES

Michael J. Murphy, DVM, PhD, DACT

SECTION III ENDOCRINE AND METABOLIC DISEASES

Mark E. Peterson, DVM, DACVIM

SECTION IV ONCOLOGY AND HEMATOLOGY

Douglas H. Thamm, VMD, DACVIM (Oncology)

SECTION V DERMATOLOGIC DISEASES

Craig E. Griffin, DVM, DACVD
Wayne S. Rosenkrantz, DVM, DACVD

SECTION VI GASTROINTESTINAL DISEASES

David C. Twedt, DVM, DACVIM (Internal Medicine)

SECTION VII RESPIRATORY DISEASES

Eleanor C. Hawkins, DVM, DACVIM

SECTION VIII CARDIOVASCULAR DISEASES

John D. Bonagura, DVM, MS, DACVIM (Cardiology, Internal Medicine)

SECTION IX URINARY DISEASES

India F. Lane, DVM, MS, DACVIM

SECTION X REPRODUCTIVE DISEASES

Margaret V. Root Kustritz, DVM, PhD, DACT

SECTION XI NEUROLOGIC AND MUSCULOSKELETAL DISEASES

Rodney S. Bagley, DVM, DACVIM (Neurology, Internal Medicine)

SECTION XII OPHTHALMIC DISEASES

David J. Maggs, BVSc, DACVO

SECTION XIII INFECTIOUS DISEASES

Rance K. Sellon, DVM, PhD, DACVIM

APPENDIX I TABLE OF COMMON DRUGS: APPROXIMATE DOSAGES

Mark G. Papich, DVM, MS, DACVCP

Gainesville, Florida;
Small Animal Surgeon
Veterinary Specialists of Rochester
Rochester, New York
Renal Transplantation

Darcy B. Adin, DVM, DACVIM (Cardiology)

Veterinary Specialists of Rochester
Rochester, New York
Tricuspid Valve Dysplasia

Verena K. Affolter, DVM, PhD

Associate Professor for Clinical Dermatopathology
Department of Pathology, Microbiology, and Immunology
School of Veterinary Medicine
University of California
Davis, California
Histiocytic Disease Complex
Nonneoplastic Nodular Histiocytic Diseases of the Skin

P. Jane Armstrong, DVM, MS, MBA, DACVIM (SAIM)

Professor, Internal Medicine/Clinical Nutrition
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Feline Inflammatory Liver Disease

Clarke E. Atkins, DVM, DACVIM (Internal Medicine, Cardiology)

Professor of Medicine and Cardiology
Veterinary Teaching Hospital
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Feline Heartworm Disease

Anne Avery, VMD, PhD

Assistant Professor
Director Clinical Immunopathology Service
Department of Microbiology, Immunology, and Pathology
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Canine Lymphoma

Sandra M. Axiak, DVM

Veterinary Specialists of North Texas and Animal Care Center
Dallas, Texas
Pulmonary Neoplasia

Todd W. Axlund, DVM, MS, DACVIM (Neurology)

Director
Metropolitan Veterinary Hospital
Akron, Ohio
Treatment of Intracranial Tumors

Rodney S. Bagley, DVM, DACVIM (Neurology, Internal Medicine)

Professor, Neurology and Neurosurgery
Department of Veterinary Clinical Sciences
Washington State University
Pullman, Washington
*Treatment of Canine Cervical Spondylomyelopathy:
A Critical Review*
Treatment of Degenerative Lumbosacral Stenosis
Vestibular Disease of Dogs and Cats

Claudia J. Baldwin, DVM, MS, DACVIM (Internal Medicine)

Associate Professor, Veterinary Clinical Sciences
College of Veterinary Medicine
Iowa State University
Ames, Iowa
Pregnancy Loss in the Queen

Tania A. Banks, BVSc, FRCVSc

Brisbane Veterinary Specialist Centre
Albany Creek, Queensland
Australia
Canine Soft-Tissue Sarcomas

Jeanne A. Barsanti, DVM, MS, DACVIM (SAIM)

Josiah Meigs Distinguished Teaching Professor
Department of Small Animal Medicine and Surgery
College of Veterinary Medicine
The University of Georgia
Athens, Georgia
Multidrug-Resistant Urinary Tract Infection

Joseph W. Bartges, DVM, PhD, DACVIM, DACVN

Professor of Medicine and Nutrition
The Acree Endowed Chair of Small Animal Research
Department of Small Animal Clinical Sciences
College of Veterinary Medicine
The University of Tennessee
Knoxville, Tennessee
Interpreting and Managing Crystalluria

Shane W. Bateman, DVM, DVSC, DACVECC

Associate Professor, Clinical
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Fluid Therapy
Ventilator Therapy

Karin M. Beale, DVM, DACVD

Staff Dermatologist
Gulf Coast Veterinary Dermatology & Allergy
Houston, Texas
Feline Demodicosis

Ellen N. Behrend, DVM, DACVIM

Associate Professor
Department of Clinical Sciences
College of Veterinary Medicine
Auburn University
Auburn, Alabama
*Interpretation of Endocrine Diagnostic Test Results for
Adrenal and Thyroid Disease*

Adrienne Bentley, DVM

Resident in Surgery
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Drainage Techniques for the Septic Abdomen

Ellison Bentley, DVM, DACVO

Clinical Associate Professor
Comparative Ophthalmology
Department of Surgical Sciences
School of Veterinary Medicine
University of Wisconsin
Madison, Wisconsin
Nonhealing Corneal Erosions in Dogs

Allyson C. Berent, DVM, DACVIM

Staff Veterinarian in Small Animal Internal Medicine
and Interventional Radiology
Waltham Lecturer: Minimally Invasive Diagnostics/
Therapeutics
Matthew J. Ryan Veterinary Teaching Hospital
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Interventional Radiology in Urinary Diseases

Philip J. Bergman, DVM, MS, PhD, DACVIM (Oncology)

Chief Medical Officer
Bright Heart Veterinary Centers
Armonk, New York
Malignant Melanoma

Adam J. Birkenheuer, DVM, DACVIM (Internal Medicine)

Assistant Professor of Internal Medicine
Department of Clinical Sciences
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Babesiosis
Thrombocytopenia

Karyn Bischoff, DVM, MS, DABVT

Diagnostic Toxicologist
Animal Health Diagnostic Center
Assistant Professor
College of Veterinary Medicine
Cornell University
Ithaca, New York
Aflatoxicosis in Dogs
Automotive Toxins

Dana R. Bleifer, DVM

Warner Center Pet Clinic
Woodland Hills, California
False Pregnancy in the Bitch

**John D. Bonagura, DVM, MS, DACVIM
(Cardiology, Internal Medicine)**

Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Management of Heart Failure in Dogs
Ventricular Septal Defect

Dino M. Bradley, DVM, MS

Research Associate
Scott-Ritchey Research Center
College of Veterinary Medicine
Auburn University
Auburn, Alabama
Acral Lick Dermatitis

Edward B. Breitschwerdt, DVM, DACVIM

Professor of Medicine and Infectious Diseases
Director, NCSU-CVM Biosafety Laboratory
Adjunct Associate Professor of Medicine
Duke University Medical Center
Department of Clinical Sciences
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Bartonellosis

**Janice M. Bright, BSN, MS, DVM, DACVIM
(Internal Medicine, Cardiology)**

Professor of Cardiology
Department of Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Cardioversion

Marjory B. Brooks, DVM, DACVIM

Associate Director, Comparative Coagulation Laboratory
Department of Population Medicine and Diagnostic Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York
Antiplatelet and Anticoagulant Therapy
Platelet Dysfunction

Cathy A. Brown, VMD, PhD, DACVP

Professor, Pathology
Athens Diagnostic Laboratory
College of Veterinary Medicine
University of Georgia
Athens, Georgia
Glomerular Disease

**Barret J. Bulmer, DVM, MS, DACVIM
(Cardiology)**

Assistant Professor
Veterinary Clinical Sciences
College of Veterinary Medicine
Oregon State University
Corvallis, Oregon
Mitral Valve Dysplasia

**Amanda Burrows, BSc, BVMS, FRCVSc
(Veterinary Dermatology)**

Veterinary Hospital
Murdoch University
Murdoch
Western Australia
Avermectins in Dermatology

Julie K. Byron, DVM, MS, DACVIM

Assistant Professor, Small Animal Medicine
Department of Clinical Medicine
University of Illinois at Urbana-Champaign
Urbana, Illinois
Urinary Incontinence: Treatment With Injectable Bulking Agents

Clay A. Calvert, DVM, DACVIM (Internal Medicine)

Professor
Department of Small Animal Medicine
College of Veterinary Medicine
University of Georgia
Athens, Georgia
Cardiomyopathy in Doberman Pinschers
Syncope

Anthony P. Carr, DrMedVet, DACIM

Associate Professor
Western College of Veterinary Medicine
University of Saskatchewan
Saskatoon, Saskatchewan
Canada
von Willebrand's Disease and Other Hereditary Coagulopathies

Elizabeth W. Carsten, DVM, DACVIM

Internal Medicine Consultant
IDEXX Laboratories, Inc.
Oro Valley, Arizona
Esophagitis

James L. Catalfamo, MS, PhD

Director, Comparative Coagulation Laboratory
Department of Population Medicine and Diagnostic Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York
Platelet Dysfunction

Daniel L. Chan, DVM, MRCVS, DACVECC, DACVN

Lecturer in Emergency and Critical Care
Department of Veterinary Clinical Sciences
The Royal Veterinary College
University of London
London, England
United Kingdom
Nutrition in Critical Care

Annie V. Chen, DVM

Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Washington State University
Pullman, Washington
*Treatment of Canine Cervical Spondylomyelopathy:
A Critical Review*

Dennis J. Chew, DVM, DACVIM (Internal Medicine)

Professor
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Idiopathic Feline Hypercalcemia
Treatment of Hypoparathyroidism
Urinary Incontinence: Treatment With Injectable Bulking Agents

Ruthanne Chun, DVM, DACVIM (Oncology)

Clinical Associate Professor
Member, University of Wisconsin Comprehensive Cancer Center
School of Veterinary Medicine
University of Wisconsin
Madison, Wisconsin
Anal Sac Tumors

Julie Churchill, DVM, PhD

Assistant Clinical Professor
Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Food Toxicoses in Small Animals

Craig A. Clifford, DVM, MS, DACVIM (Oncology)

Staff Oncologist
Red Bank Veterinary Hospital
Tinton Falls, New Jersey
Canine Hemangiosarcoma

Joan R. Coates, DVM, MS, DACVIM (Neurology)

Associate Professor
Veterinary Medicine and Surgery
Neurology/Neurosurgery Service Leader
Veterinary Medical Teaching Hospital
Department of Veterinary Medicine and Surgery
College of Veterinary Medicine
University of Missouri
Columbia, Missouri
Treatment of Animals With Spinal and Musculoskeletal Pain

Leah A. Cohn, DVM, PhD, DACVIM (SAIM)

Associate Professor of Veterinary Internal Medicine
Department of Veterinary Medicine and Surgery
College of Veterinary Medicine
University of Missouri
Columbia, Missouri
Canine Anaplasma Infection

Lynette K. Cole, DVM, MS, DACVD

Assistant Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Systemic Therapy for Otitis Externa and Media

Patrick Concannon, MS, PhD, DACT (Honorary)

Visiting Fellow, Department of Clinical Sciences
Director
Laboratory for Comparative Reproduction Studies
Department of Biomedical Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York
Estrus Suppression in the Bitch

Gheorge M. Constantinescu, DVM, PhD, Drhc

Professor of Veterinary Anatomy
College of Veterinary Medicine
University of Missouri
Columbia, Missouri
Brachycephalic Upper Airway Syndrome in Dogs

Johanna C. Cooper, BSc, DVM, DACVIM

Cape Cod Veterinary Specialists
Buzzards Bay, Massachusetts
Diagnostic Approach to Hepatobiliary Disease

Brendan M. Corcoran, MVB, DipPharm, PhD, MRCVS

Senior Lecturer
Hospital for Small Animals
Division of Veterinary Clinical Studies
The University of Edinburgh
Easterbush Veterinary Centre
Edinburgh, Scotland
United Kingdom
Interstitial Lung Diseases

Etienne Côté, DVM, DACVIM (Cardiology, SAIM)

Assistant Professor
Department of Companion Animals
Atlantic Veterinary College
University of Prince Edward Island
Charlottetown, Prince Edward Island
Canada
Feline Cardiac Arrhythmias

Nancy B. Cottrill, DVM, MS, DACVO

Staff Ophthalmologist
Angell Animal Medical Center, Western New England
Woburn, Massachusetts
Differential Diagnosis of Anisocoria

Dennis T. Crowe, Jr., DVM, NREMT-I, PI, CFF, DACVS, DACVECC

President
Veterinary Surgery, Emergency and Critical Care Services and Consulting
Bogart, Georgia
Oxygen Therapy

Autumn P. Davidson, DVM, MS, DACVIM (Internal Medicine)

Clinical Professor
School of Veterinary Medicine
University of California
Davis, California
Canine Brucellosis
Dystocia Management

Thomas K. Day, DVM, MS, DACVECC, DACVA
Owner
Louisville Veterinary Specialty & Emergency Services
Louisville, Kentucky
Intravenous Anesthetic and Analgesic Techniques

Douglas J. DeBoer, DVM, DACVD
Professor
Department of Medical Sciences
School of Veterinary Medicine
University of Wisconsin
Madison, Wisconsin
Treatment of Dermatophytosis

Linda J. DeBowes, DVM, MS, DACVIM, DAVDC
Shoreline Veterinary Dental Clinic
Seattle, Washington
Feline Caudal Stomatitis

**Louis-Philippe de Lorimier, DVM, DACVIM
(Oncology)**
Staff Medical Oncologist
Hôpital Vétérinaire Rive-Sud
Brossard, Québec
Canada
Canine Hemangiosarcoma

**Helio Autran de Moraes, DVM, PhD, DACVIM
(SAIM, Cardiology)**
Clinical Associate Professor
Department of Medical Sciences
University of Wisconsin
Madison, Wisconsin
Acid-Base Disorders

Robert C. DeNovo, DVM, MS, DACVIM
Professor and Head
Department of Small Animal Clinical Sciences
College of Veterinary Medicine
University of Tennessee
Knoxville, Tennessee
Canine Megaesophagus

**Curtis W. Dewey, DVM, MS, DACVIM
(Neurology), DACVS**
Associate Professor, Neurology/Neurosurgery
Neurology/Neurosurgery Service Chief
Cornell University Hospital for Animals
Cornell University
Ithaca, New York
New Maintenance Anticonvulsant Therapies for Dogs and Cats
Traumatic Brain Injury
Treatment of Canine Chiari-Like Malformation and Syringomyelia

**Anna R. Deykin, BSc, BVMS, FRCVSc
(Ophthalmology)**
Veterinary Ophthalmologist
Brisbane Veterinary Specialist Centre
Brisbane, Queensland
Australia
Episcleritis and Scleritis in Dogs

Stephen P. DiBartola, DVM, DACVIM (SAIM)
Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Acid-Base Disorders
Fluid Therapy

**Patricia M. Dowling, DVM, MSc, DACVIM,
DACVCP**
Professor, Veterinary Clinical Pharmacology
Western College of Veterinary Medicine
University of Saskatchewan
Veterinary Biomedical Sciences
Saskatoon, Saskatchewan
Canada
Rational Empiric Antimicrobial Therapy

**Kenneth J. Drobatz, DVM, MS, DACVIM,
DACVECC**
Director of the Emergency Service
Chief of Critical Care Section
Matthew J. Ryan Veterinary Hospital
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Noncardiogenic Pulmonary Edema
Urethral Obstruction in Cats

Preface

This new edition of *Kirk's Current Veterinary Therapy* is the fourteenth version of a textbook used by generations of practicing veterinarians and veterinary students. The general format and chapter presentation of this edition should be familiar to long-time users of "CVT". For our new readers it is my hope that you find the information in this textbook (and the related CVT website) both informative and accessible. Foremost, I hope CVT will help you provide the best possible care for your canine and feline patients. Whereas the overall format of this new edition follows the original formula outlined by Dr. Robert W. Kirk, there are also changes and enhancements.

As the title suggests, the focus of most chapters is therapy of important medical diseases of dogs and cats. *Current Veterinary Therapy* is divided into thirteen sections and three appendices. The sections are organized by organ system, including cardiovascular, dermatologic, gastrointestinal, hematologic, neurologic and musculoskeletal, ophthalmologic, reproductive, respiratory, and urinary diseases. Multisystemic diseases are detailed in the sections covering critical care medicine, infectious diseases, oncology and hematology, and toxicology. Appendix I, *Table of Common Drugs: Approximate Dosages*, and the tables in Appendix II, *Treatment of Parasites*, have been completely revised for this edition. Of great importance is the oversight provided by one or more specialists who served as Consulting Editor for each of these sections. I am most grateful to these outstanding clinicians for their guidance and editorial input.

It is worthwhile to highlight some of the changes adopted for this edition. Foremost has been the inclusion of an Associate Editor, Dr. David Twedt. Dave is recognized worldwide as an outstanding internist, gastroenterologist, and educator. I am most appreciative of his excellent editorial work, and have benefitted greatly from the perspective he brought to this volume. We also recruited some outstanding new Consulting Editors for this edition, while retaining the services of some of the most respected authorities in small animal medicine. Another change involved rearranging sections. Gone is the section on *Diseases of Birds and Exotic Pets*. In recent years these areas have exploded in terms of knowledge and practices, as demonstrated by the proliferation of complete textbooks covering these subjects. After some discussion, it was decided that CVT should now concentrate on canine and feline patients. Additionally, the *Special Therapy* section has been eliminated and its topics moved into the most relevant sections for those treatments. The former *Cardiopulmonary Diseases* section has been reasonably divided into two sections: *Cardiovascular Diseases* and *Respiratory Diseases*.

In keeping with current and still-evolving publishing practices, we have made one major change to the fourteenth edition in the guise of a *Current Veterinary Therapy* website. Owners of this textbook will have password access to this electronic content, which resides on the Elsevier Evolve website (<http://evolve.elsevier.com/Bonagura/Kirks/>). We have included on this site chapters from the thirteenth edition that we believe are still useful to our readers. A number of these chapters have been updated by the original authors. These "still-current" chapters are organized by section along the same lines as the textbook. Additionally, the website contains an image library of figures printed in this new edition, with additional images also available in color. Website users can access an online, searchable index (citing chapters in both the current edition and CVT XIII). Appendices I-III from the textbook will also be provided in a searchable format on Evolve. Finally, we have made the decision to free up more pages for published chapters by moving some of the appendices to the Evolve website. Many of these tables relate to reference values, which we realize are often instrument and laboratory specific. Nevertheless, the interested reader will find a number of useful tables of laboratory results and values in the appendices on the website. The development of a CVT website also provides an avenue for disseminating information to readers between editions, for example, should issues arise related to drug use or dosage (a real concern with many extra-label uses of drugs in veterinary practice).

Current Veterinary Therapy XIV contains 286 published chapters and three appendices, with contributions by hundreds of authors active in their respective clinical specialties. I am indebted to these individuals for providing concise and clinically useful chapters for the current edition. We have tried to maintain the historical format of Kirk's chapters that considers the salient clinical features of a disease or disorder, the basis for rational therapy, and clear and practical pointers for treatment, while also addressing pending innovations in therapy. As stated above, most chapters are directed toward management of a specific condition. Others concentrate on important principles of therapy or general management approaches to diseases of dogs and cats. With the rapid development of knowledge across our diverse profession, we have undoubtedly omitted some topics. Treatment of some of these may have changed little in the past 5 years. Others are simply beyond our scope (or page allotment) or may be better covered elsewhere. This is especially true of specific surgical procedures, a subject area in which CVT provides only limited guidance.

The fastest way to find information in *Current Veterinary Therapy* is through the index. The index is organized to

emphasize diseases based on anatomic and physiologic disorders and is extensively cross-referenced. Using either the index printed in the textbook or the online version on the website, the reader should be able to locate a concise chapter detailing the most important medical problems of dogs and cats. Many readers familiar with the *CVT* format will probably head straight for the individual sections' tables of content to peruse the section contents. Related chapters located on the Evolve website are also listed there. As some subjects "overlap" individual sections, we have made every attempt to cross-index information in chapters throughout the book.

Current Veterinary Therapy is written for both the veterinary practitioner and the veterinary student. It is my hope that *CVT* will be discovered by students who will later find its contents an asset to their professional work. I am always grateful to receive comments from readers, including any concerns about possible errors or omissions. Ideas designed to improve this textbook are most welcome. As I have written previously, I have tried to maintain *CVT* on the course first set by Dr. Kirk. I remain most appreciative of your acceptance of previous editions and this new one.

ACKNOWLEDGMENTS

I would like to acknowledge a number of individuals. I am most thankful to the veterinarians and scientists who have contributed to this edition and to the expertise and

oversight of our Consulting Editors. Bringing Dr. David Twedt on board has been very helpful, and the book is far better for his efforts. I am especially appreciative of Jolynn Gower, Managing Editor at Elsevier. Without Jolynn's sustained efforts and encouragement, this edition would still be on my desktop (real and electronic). Publisher Penny Rudolph has provided helpful oversight and counsel throughout this endeavor, and I appreciate her patient support. Karen Rehwinkel, Senior Project Manager at Elsevier, has most ably handled the hundreds of manuscripts, electronic documents, authors' information, and page proofs to somehow create this volume. Liz Fathman, my former editor at Elsevier, was most helpful in getting this project started. Others at Elsevier, with whom I have not worked directly, have been important in creating this textbook, and I extend my deepest appreciation to them. Special thanks are extended to Debra Primovic, DVM, for indexing this and the previous volume of *CVT*.

John D. Bonagura, DVM

CHAPTER 1

Shock

ANNIE MALOUIN, *Philadelphia, Pennsylvania*

DEBORAH SILVERSTEIN, *Philadelphia, Pennsylvania*

Shock is a state of severe hemodynamic and metabolic derangements. It is characterized by poor tissue perfusion from low or unevenly distributed blood flow that leads to a critical decrease in oxygen delivery (DO_2) in relation to oxygen consumption (VO_2) (Fig. 1-1) and/or inadequate cellular energy production. If the shock state is not promptly recognized and treated, neurohormonal compensatory mechanisms will lead to stimulation of the renin-angiotensin-aldosterone system, as well as baroreceptor and chemoreceptor-mediated release of catecholamines and subsequent production of counterregulatory hormones (glucagon, adrenocorticotrophic hormone [ACTH], and cortisol). These changes will increase cardiovascular tone, activate a variety of biochemical mediators, and stimulate inflammatory responses that contribute to the shock syndrome. This progression can cause or exacerbate uneven microcirculatory flow, poor tissue perfusion, tissue hypoxia, altered cellular metabolism, cellular death, and vital organ dysfunction or failure.

Box 1-1 lists the different types of shock, but this classification can be overly simplistic. Critically ill patients are subject to complex etiologic and pathophysiologic events and therefore may suffer from more than one type of shock simultaneously. The rationale for the functional classification of shock is the presumption that each underlying illness identified can be associated with a specific pathophysiologic process and rapid, appropriate therapy can be administered.

CLINICAL PRESENTATION

Dogs in compensatory shock demonstrate mild-to-moderate mental depression, increased heart rate, increased respiratory rate, peripheral vasoconstriction with cold extremities and pale mucous membranes, and a shortened capillary refill time with normal blood pressure. As compensatory mechanisms fail, they may develop severe mental depression, prolonged capillary refill time, increased heart rate, poor pulse quality, and decreased arterial blood pressure.

Dogs with sepsis or a systemic inflammatory response syndrome (SIRS) can show clinical signs of hyperdynamic or hypodynamic shock. The initial hyperdynamic phase of sepsis is characterized by tachycardia, fever, bounding peripheral pulse quality, and hyperemic mucous membranes secondary to peripheral vasodilation. If septic shock or SIRS progresses unchecked, a decreased cardiac

output and signs of hypoperfusion may ensue as a result of cytokine effects on the myocardium or myocardial ischemia. Clinical alterations may then include tachycardia, pale (and possibly icteric) mucous membranes with a prolonged capillary refill time, hypothermia, poor pulse quality and dull mentation. Hypodynamic septic shock is the decompensatory stage of sepsis and without intervention will result in organ damage and death. Finally, the gastrointestinal (GI) tract is the shock organ in dogs and often leads to ileus, diarrhea, or melena.

In cats the hyperdynamic phase of shock is rarely recognized. Also, in contrast to dogs, changes in heart rate in cats with shock are unpredictable; they may exhibit tachycardia or bradycardia. In general, cats typically present with pale mucous membranes (and possibly icterus), weak pulses, cool extremities, hypothermia, and generalized weakness or collapse. In cats the lungs seem to be the organ most vulnerable to damage during shock or sepsis, and signs of respiratory dysfunction are common (Schutzer et al., 1993; Brady et al., 2000; Costello et al., 2004).

MANAGEMENT

General Diagnostics

For all patients in shock, basic diagnostic tests should be completed to assess the extent of organ injury and identify the etiology of the shock state. Venous or arterial blood gases, a complete blood cell count, blood chemistry panel, coagulation panel, blood typing, and urine analysis should be performed in all shock patients. Thoracic and abdominal radiographs, abdominal ultrasound, and echocardiography may be indicated once the patient is stabilized. Thoracic imaging can help distinguish cardiogenic forms of shock.

Monitoring Perfusion and Oxygen Delivery

The magnitude of oxygen deficit is a key predictor in determining outcome in patients with shock. Therefore optimizing tissue perfusion and DO_2 is the goal of effective therapy, and thorough monitoring is necessary to achieve this objective. An optimally perfused patient maintains the following characteristics: central venous pressure between 5 and 10 cm H_2O (2 to 5 cm H_2O in cats); urine production of at least 1 ml/kg/hour; a mean arterial pressure (MAP) between 70 and 120 mm Hg; normal body

Fig. 1-1 The relationship between oxygen delivery and oxygen consumption. In region B-C the oxygen consumption remains constant as oxygen delivery is increased. The oxygen supply is in excess of consumption, and VO_2 is termed *supply independent*. During shock, as metabolic demand (VO_2) increases or DO_2 diminishes (C-B), Oxygen extraction ratio rises to maintain aerobic metabolism; thus consumption can remain independent of delivery. However, at point B, called *critical DO_2 (DcO_2)*, the maximum OER is reached. This is believed to be 60% to 70%, and beyond this point any further increase in VO_2 or decline in DO_2 must lead to tissue hypoxia.

Box 1-1

Functional Classifications and Examples of Shock

Hypovolemic: A Decrease in Circulating Blood Volume

- Hemorrhage
- Severe dehydration
- Trauma

Cardiogenic: A Decrease in Forward Flow From the Heart

- Congestive heart failure
- Cardiac arrhythmia
- Cardiac tamponade
- Drug overdose (e.g., anesthetics, β -blockers, calcium channel blockers)

Distributive: A Loss of Systemic Vascular Resistance

- Sepsis
- Obstruction (heartworm disease, saddle thrombosis)
- Anaphylaxis

Metabolic: Deranged Cellular Metabolic Machinery

- Hypoglycemia
- Cyanide toxicity
- Mitochondrial dysfunction
- Cytopathic hypoxia of sepsis

Hypoxemic: A Decrease in Oxygen Content in Arterial Blood

- Anemia
- Severe pulmonary disease
- Carbon monoxide toxicity
- Methemoglobinemia

temperature, heart rate, heart rhythm, and respiratory rate; and moist, pink mucous membranes with a capillary refill time of less than 2 seconds. Monitoring these parameters becomes the baseline of patient assessment. Additional monitoring elements that may prove beneficial include measuring blood lactate, indices of systemic oxygenation transport, and mixed venous oxygen saturation.

Blood Lactate Levels

Critically ill patients with inadequate tissue perfusion, DO_2 , or oxygen uptake, often have a hyperlactatemia and acidemia that reflect the severity of tissue hypoxia. Humans with lactic acidosis are at greater risk of developing multiple organ failure and demonstrate a higher mortality rate than patients without an elevated lactate concentration (Nguyen et al., 2004). High blood lactate levels may also help to prognosticate mortality in dogs (Boag and Hughes, 2005; de Papp E et al., 1999; Nel et al., 2004; Lagutchik et al., 1998). The normal lactate level in adult dogs and cats is reported to be less than 2.5 mmol/L; lactate concentrations greater than 7 mmol/L are considered severely elevated (Boag et al., 2005). However, normal neonatal and pediatric patients may have higher lactate concentrations (McMichael et al., 2005). In addition, sample collection and handling techniques can affect lactate concentration (Hughes et al., 1999). Serial lactate measurements can be taken during the resuscitation period to gauge response to treatment and evaluate the resuscitation end points; the trends in lactate concentrations are a better predictor of outcome than are single measurements. It is well documented that the ability of the body to correct an elevated lactate concentration is directly correlated to survival.

Cardiac Output Monitoring and Indices of Oxygen Transport

The most direct way to assess the progress of resuscitation in shock patients is to measure indices of systemic oxygen transport. Measurement and monitoring of these values requires right-sided cardiac catheterization, which is performed using a specialized pulmonary artery catheter (PAC, also termed *Swan-Ganz catheter* or *balloon-directed thermodilution catheter*). The PAC allows access for the measurement of central venous and pulmonary arterial pressure, mixed venous blood gases (PvO_2 and SvO_2), pulmonary capillary wedge pressure (PCWP), and cardiac output. With these data additional information regarding the function of the circulatory and respiratory systems can be derived (i.e., stroke volume, end-diastolic volume numbers, systemic vascular resistance index, pulmonary vascular resistance index, arterial oxygen content, mixed venous oxygen content, DO_2 index, VO_2 index and the oxygen extraction ratio). The cardiac output is most commonly determined using thermodilution methods, although other techniques are available, including non-invasive Doppler-based methods.

A PAC can provide the clinician with useful information to assess and monitor the cardiovascular and pulmonary function of shock patients. It may also help the clinician evaluate the response to therapeutic interventions and allow titration of fluid therapy, vasopressors,

and inotropic agents. Cardiac output and systemic DO_2 should be optimized by intravascular volume loading until the PCWP approaches 18 to 20 mm Hg. A higher PCWP (>18 -20 mm Hg) promotes the formation of pulmonary edema; further impairing oxygenation and overall oxygen transport. In critically ill humans the cardiac index (CI), DO_2 , and VO_2 have been found to be higher in survivors. Finally, the use of a PAC does not necessarily translate into reduced mortality in the critically ill shock patient; it is an invasive monitoring technique that is not without risk. Despite the fact that a tremendous amount of information can be obtained from the PAC, it is important to recognize that the accuracy of the measurements provided by the PAC rely on catheter placement, calibration of transducers, coexisting cardiac or pericardial disease, and interpretation of waveforms and measurements or calculations. PAC placement should be performed by experienced individuals, and interpretation of the data should be systematic. In humans the most common complications that occur during or after PAC insertion include arrhythmias, pulmonary injuries, thromboembolism, and sepsis.

Mixed Venous Oxygen Saturation and Central Venous Oxygen Saturation

Mixed venous oxygen saturation (SvO_2) can be used clinically to assess changes in the global tissue oxygenation (oxygen supply-to-demand). If VO_2 is constant, SvO_2 is determined by cardiac output, hemoglobin concentration, and systemic arterial oxygen tension. The SvO_2 is decreased if DO_2 is decreased (low cardiac output, hypoxia, severe anemia) or if VO_2 is increased (fever). SvO_2 is increased in hyperdynamic stages of sepsis and cytotoxic tissue hypoxia (e.g., cyanide poisoning). A reduction in SvO_2 may be an early sign that the patient's clinical condition is deteriorating. Also, SvO_2 may be a surrogate for measuring the CI during resuscitative efforts.

Ideally SvO_2 is measured in a blood sample from the pulmonary artery. However, in cases in which the insertion of a PAC is not possible or desirable, SvO_2 can be determined in the central circulation, using a central venous catheter in the cranial vena cava. SvO_2 is then termed *central venous oxygen saturation* (ScvO_2). In critically ill patients with circulatory failure of any origin, ScvO_2 values generally are higher than SvO_2 , but the two measurements closely parallel one another. Therefore the presence of a pathologically low ScvO_2 likely indicates an even lower SvO_2 . The difference between the two values is usually about 5%; this is caused by the effect of blood flow redistribution and differences in oxygen consumption across the hepatosplanchnic, coronary, and cerebral circulations during shock states. Finally, a recent prospective randomized study comparing two algorithms for early goal-directed therapy in patients with severe sepsis and septic shock showed that maintenance of a continuously measured ScvO_2 above 70% (in addition to maintaining central venous pressure above 8 to 12 mm Hg, MAP above 65 mm Hg, and urine output above 0.5 ml/kg/hour) resulted in a 15% absolute reduction in mortality compared to the same treatment without ScvO_2 monitoring (see following paragraphs for further details) (Rivers et al., 2001).

THERAPY

If the animal is not breathing or displays signs of impending fatigue, immediate intubation and positive-pressure ventilation should be instituted. If the animal is breathing spontaneously, oxygen is administered. This can involve flow-by methods (50 to 150 ml/kg/minute) such as simply holding the oxygen tubing up to the nose or administration of oxygen into a mask, hood, or bag. Nasal catheter(s) are effective methods of oxygen administration (using rates of 50 to 100 ml/kg/minute per catheter). Once the vital signs are obtained, vascular access is established, and fluid administration is initiated if indicated. It is of utmost importance that preliminary diagnostics and appropriate treatment are rapidly initiated to maximize DO_2 to the tissues and prevent irreversible shock.

Fluid Therapy

Vascular Access

The first and most important therapeutic goal for non-cardiogenic shock is to restore the effective circulatory volume. Appropriate vascular access is essential for rapid administration of large volumes of fluid (see Chapter 7 for further details). Poiseuille's law of flow states that resistance to flow through a catheter is directly proportional to the length of the catheter and inversely related to the fourth power of the radius. Thus large-bore, short intravenous catheters should be placed for resuscitation. For cats and small dogs 18- or 20-gauge catheters should be used; for larger dogs multiple venous catheters (14- to 18-gauge) should be placed. Faster intravenous fluid administration can be further facilitated by applying pressure around the fluid bag with a commercial pressure device or a blood pressure cuff.

Crystalloids

Isotonic crystalloids remain the cornerstone of treatment for noncardiogenic shock. Examples include 0.9% sodium chloride, lactated Ringer's solution, Normosol-R, and Plasmalyte-148. A shock dose of isotonic crystalloid solution is approximately one blood volume (i.e., 90 ml/kg in the dog and 50 ml/kg in the cat). The fluid administered rapidly distributes into the extracellular fluid compartment so that only $\approx 25\%$ of the delivered volume remains in the intravascular space by 30 minutes after infusion (Silverstein et al., 2005). Although theoretically this increase in interstitial fluid volume might predispose to interstitial edema and deranged oxygen transfer to the cells, this has not been proven in human clinical trials. However, it is important that excessive fluid volumes are not administered to avoid volume overload. It is generally recommended that one third to one half of the shock dose be administered as quickly as possible, followed by additional boluses as indicated by clinical parameters and repeated physical examination. In patients that are bleeding it may even be advantageous to perform "hypotensive resuscitation" (to a MAP of ≈ 60 mm Hg) until the hemorrhage is controlled since aggressive fluid therapy in this setting can worsen bleeding and outcome. For animals with coexisting head trauma, the

isotonic crystalloid of choice is 0.9% NaCl since it contains the highest concentration of sodium and is least likely to contribute to cerebral edema.

Hypertonic Solutions

Hypertonic (7% to 7.5%) sodium chloride administration causes a transient osmotic shift of water from the extravascular to the intravascular compartment. It is administered in small volumes (5 ml/kg) intravenously (IV) over 5 to 10 minutes. In addition to the fluid compartment shift caused by hypertonic saline, there is evidence that it may also be beneficial to reduce endothelial swelling, increase cardiac contractility, cause mild peripheral vasodilation, and decrease intracranial pressure. Because of the osmotic diuresis and rapid redistribution of the sodium cations that ensue following the administration of hypertonic saline, the intravascular volume expansion is transient (<30 minutes), and additional fluid therapy must be used with hypertonic saline (Silverstein et al., 2005). Hypertonic saline may be administered in conjunction with synthetic colloids.

Synthetic Colloids

Colloids are large molecules (molecular weight >20,000 daltons) that do not readily sieve across the vascular membrane. The colloidal particles in the most commonly used synthetic colloids (dextran 70 and hydroxyethyl starch) are suspended in 0.9% NaCl. They are hyperoncotic to the normal animal and therefore pull fluid into the vascular space. They cause an increase in blood volume that is greater than that of the infused volume and help to retain this fluid in the intravascular space in animals with normal capillary permeability. Dextran 70 is a 6% colloidal solution with particles that range from 15,000 to 3,400,000 daltons, a number average molecular weight of 41,000, and a colloid osmotic pressure of 60 mm Hg. Hetastarch is also a 6% solution with particles ranging from 10,000 to 1,000,000 daltons in molecular weight, a number average molecular weight of 69,000 daltons, and a colloid osmotic pressure of 34 mm Hg. The recommended dose of synthetic colloids for the treatment of shock is up to 20 ml/kg in the dog and up to 10 ml/kg in the cat (note that rapid administration of hydroxyethyl starch in the cat has been reported to cause vomiting). Excessive volumes can lead to volume overload, coagulopathies, and hemodilution. These fluids are appropriately used for shock therapy in acutely hypoproteinemic animals (total protein less than 3.5 g/dl) with a decreased colloid osmotic pressure. They can also be used with isotonic or hypertonic crystalloids to maintain adequate plasma volume expansion with lower interstitial fluid volume expansion and to expand the intravascular space with smaller volumes over a shorter time period. Despite multiple clinical studies in humans, there is no definitive documentation that the use of colloids is superior to the use of crystalloids for resuscitation, and the price of colloids is significantly greater than that of crystalloids (for further details, see Chapter 11).

Hypertonic Saline Plus Synthetic Colloid Solutions

To prolong the effect of the resuscitation fluids, a hypertonic saline/synthetic colloid (dextran 70 or hydroxyethyl starch) mixture can be administered for the treatment of

shock. A 1:2.5 ratio of 23.4% NaCl with dextran 70 or hetastarch makes an ≈7.5% saline mixture (44 ml of 23.4% NaCl in 106 ml of dextran 70 or hydroxyethyl starch).

Blood Component Therapy

The need for blood products during resuscitation relates to the patient's disease process. Most fluid-responsive shock patients tolerate acute hemodilution to a hematocrit of less than 20%. In animals with acute blood loss that are unresponsive to fluid therapy alone, the hematocrit should be maintained at more than 25% to 30% to maximize oxygen-carrying capacity. Excessive increases in hematocrit should be avoided since this will increase blood viscosity. Most animals can tolerate an acute loss of 10% to 15% of blood volume without requiring a blood transfusion. Acute hemorrhage exceeding 20% of the blood volume often requires transfusion therapy in addition to the initial fluid resuscitation discussed previously. In animals with acute blood loss requiring transfusion therapy, fresh whole blood or packed red blood cells and fresh frozen plasma should be used in an attempt to stabilize clinical signs of shock and maintain the hematocrit above 25% and clotting times within the normal range.

Packed red blood cells and fresh frozen plasma are administered at a dose of 10 to 15 ml/kg, and fresh whole blood at a dose of 20 to 25 ml/kg. Refrigerator-stored plasma or frozen plasma that is more than 1 year old no longer contains platelets or the labile coagulation factors (V, VIII, and von Willebrand). Platelets are only present in fresh blood within 6 hours of collection, and their use is indicated in animals with thrombocytopenia/thrombocytopathia-induced bleeding disorders or massive hemorrhage. Plasma products are most commonly used in animals with profound blood loss, a coagulopathy, or severe hypoalbuminemia. The ability of these products to increase colloid osmotic pressure is limited compared to the hyperoncotic synthetic colloids. However, blood products do supply albumin, an important carrier of certain drugs, hormones, metals, chemicals, toxins, and enzymes. Blood products generally should be administered over at least 1 to 2 hours to monitor for a transfusion reaction and avoid volume overload, but it may be necessary to bolus these products in life-threatening situations. A blood type should be determined in all animals, especially cats, before transfusions are given. Crossmatching also helps to decrease the incidence of transfusion reactions.

Human Serum Albumin Solution

Animals with severe hypoalbuminemia may benefit from treatment with 25% human albumin. Albumin is crucial in the transport of drugs, hormones, chemicals, toxins, and enzymes. Preliminary studies in dogs show that human albumin administration in dogs increases circulating albumin concentrations, total solids, and colloid osmotic pressure, although the effect on mortality remains unknown. Current and future studies will provide more information regarding the use of this product. Potential risks are similar to those for any blood transfusion (i.e., fever, vomiting, increased respiratory effort) in addition to the potential for increasing clotting times.

Recent reports of albumin-induced anaphylaxis in normal dogs require further investigation (Mathews and Barry, 2005).

Vasopressors and Positive Inotropes

Shock patients that remain hypotensive despite intravascular volume resuscitation often require vasopressor and/or inotrope therapy. Since both cardiac output and systemic vascular resistance affect DO_2 to the tissues, therapy for hypotensive patients includes maximizing cardiac function with fluid therapy and inotropic drugs and/or modifying vascular tone with vasopressor agents. This is particularly important in cardiogenic shock (see Chapter 171). Commonly used vasopressors include catecholamines (epinephrine, norepinephrine, and dopamine) and the sympathomimetic drug phenylephrine. In addition, vasopressin, corticosteroids, and glucagon have been used as adjunctive pressor agents.

Different sympathomimetics cause various changes in the cardiovascular system, depending on the specific receptor stimulation caused by the drug. Conventionally adrenergic receptor location and function involve the α -1 and β -2 receptors located on the vascular smooth muscle cells that lead to vasoconstriction and vasodilation, respectively, whereas β -1 receptors in the myocardium primarily modulate inotropic and chronotropic activity. In addition, there are dopaminergic-1 receptors in the renal, coronary, and mesenteric microvasculature that mediate vasodilation and dopaminergic-2 receptors in the synaptic nerve terminals that inhibit the release of norepinephrine.

Dopamine has various potential actions on adrenergic and dopaminergic receptors. Primarily dopaminergic effects are seen at low intravenous dosages (1 to 5 mcg/kg/minute); mainly β -adrenergic effects are seen at moderate dosages (5 to 10 mcg/kg/minute); mixed α - and β -adrenergic effects are present at high dosages (10 to 15 mcg/kg/minute); and primarily α -adrenergic effects are seen at very high dosages (15 to 20 mcg/kg/minute). The actual dose-response relationship is unpredictable in a given patient because it depends on individual variability in enzymatic dopamine inactivation, receptor down-regulation, and the degree of autonomic derangement. Dopamine can be used as a single-agent therapy to provide both inotropic and pressor support in animals with vasodilation and decreased cardiac contractility. In comparison to other pressor drugs, dopamine is a less potent inotrope than epinephrine (or dobutamine) and less vasoconstricting than norepinephrine. The cardiovascular effects of dopamine may dissipate after several days of therapy, perhaps because of receptor down-regulation and/or induction of increased postsynaptic norepinephrine release. Despite the beneficial effects of dopamine on cardiac output and blood pressure, it may have deleterious effects on renal, mesenteric, and skeletal blood flow.

Norepinephrine (NE) has mixed α - and β -adrenergic receptor agonist effects with preferential α -receptor activity. Therefore the effects on heart rate and contractility are mild, and NE is commonly used as a pressor agent in animals with normal or increased cardiac output states. Canine septic shock models have demonstrated that the

effects of NE on cardiac function are diminished compared to those of nonseptic controls. In septic patients with cardiac insufficiency and vasodilation, it may be desirable to use NE in conjunction with dobutamine (a potent β -agonist) to prevent the deleterious effects of increasing afterload in the face of a diseased heart. Renal blood flow may improve in animals with septic shock so long as arterial blood pressure is normalized. Conversely, NE administration to dogs with hypovolemic shock induces deleterious renal vasoconstriction. NE was also shown to improve urine output and creatinine clearance when added to dopamine or dobutamine in human patients with septic shock. Enhanced splanchnic DO_2 and increases in gastric mucosal pH are evident in humans who receive NE therapy for the treatment of hypotensive septic shock. The vasopressor dosage of NE in humans (and extrapolated to dogs) is 0.05 to 3.3 mcg/kg/minute IV.

Epinephrine (Epi) is a potent pressor with mixed α - and β -agonist activity. Although Epi is thought to have more potent β -agonist effects than NE, individual response is quite variable in patients with systemic inflammatory diseases and hypotension. Epi may significantly impair splanchnic blood flow compared to norepinephrine and dobutamine (in combination). This is most likely because of the strong α -adrenergic activity of Epi with subsequent vasoconstriction in regional vascular beds, although Epi also activates vasodilatory β -receptors. The vasopressor dosage of intravenous Epi is 0.01 to 0.1 mcg/kg/minute and for primarily β -agonist effects 0.005 to 0.02 mcg/kg/minute. Epi is rarely used as a sole first-line vasopressor agent because of its potential side effects, but it may be necessary in critically ill animals. Epi also inhibits mast cell and basophil degranulation and therefore is the drug of choice in patients suffering from anaphylactic shock. It is also commonly used for the treatment of cardiac arrest.

Phenylephrine is a pure α -agonist drug that causes profound vasoconstriction. It has been shown to cause an increase in cardiac output and blood pressure, presumably as a result of increased venous return to the heart and activation of α -1 receptors in the myocardium. Typically phenylephrine is used in patients that are unresponsive to other sympathomimetics, although it can be used as a sole first-line agent in vasodilated, hypotensive animals. Since phenylephrine has no β -agonist activity, it is the least arrhythmogenic of the sympathomimetic pressor drugs and therefore is desirable in animals that develop tachyarrhythmias in response to other pressor agents. The intravenous dosage range is 0.5 to 3 mcg/kg/minute.

Dobutamine is a β -agonist with weaker, dose-dependent α -effects. It increases cardiac output, DO_2 , and VO_2 without causing vasoconstriction at lower doses. Therefore it is useful in animals with shock caused by cardiac insufficiency. Dobutamine may worsen or precipitate tachyarrhythmias and may precipitate seizure activity in cats. The intravenous dosage range is 1 to 5 mcg/kg/minute in cats and 2.5 to 20 mcg/kg/minute in dogs.

Vasopressin is a nonadrenergic vasopressor agent. It has both direct and indirect effects on the vascular smooth muscle via the V1 receptors and induces

vasoconstriction in most vascular beds. In vitro vasopressin is a more potent vasoconstrictor than phenylephrine or NE. At low doses this drug causes vasodilation in renal, pulmonary, mesenteric, and cerebral vasculature in an attempt to maintain perfusion to these vital organs. Low flow states secondary to hypovolemia or septic shock are associated with a biphasic response in endogenous serum vasopressin levels. There is an early increase in the release of vasopressin from the neurohypophysis in response to hypoxia, hypotension, and/or acidosis, which leads to high levels of serum vasopressin. This plays a role in the stabilization of arterial pressure and organ perfusion in the initial stages of shock. There appears to be a subsequent decrease in circulating vasopressin levels, most likely a result of a depletion of hypothalamic stores. Therefore the use of vasopressin in animals in the later stages of shock, especially those that exhibit vasodilation and are refractory to catecholamine therapy, may be beneficial. The drug also enhances sensitivity to catecholamines and therefore may allow the dose of concurrent catecholamine therapy to be lowered. Experimental studies in dogs have demonstrated an increase in blood pressure and cardiac output with minimal side effects. A clinical case series using vasopressin at 0.5 to 4 mU/kg/minute found an increase in blood pressure following vasopressin therapy as well. This drug will require further investigation but may be considered in animals with catecholamine-resistant vasodilatory shock.

Glucagon typically is secreted from the pancreas and is classified as a counterregulatory hormone. It activates adenylate cyclase independent of β -adrenergic receptor stimulation. Exogenously administered glucagon causes a positive inotropic effect that leads to an increase in cardiac output and blood pressure. This drug may be useful in critically ill patients that are unresponsive to β -agonist drugs or those receiving sympathomimetic therapy that is complicated by β -blocker agents. Further research is needed.

Antimicrobials

Early antibiotic therapy is important in shock patients with proven or suspected sepsis. If possible, properly collected cultures of blood, urine, respiratory secretions (collected by endotracheal wash, transtracheal wash, or bronchoscopy) and other available body fluids (i.e., pleural, peritoneal, or cerebrospinal fluid) should be sampled carefully before antimicrobial therapy is begun. Broad-spectrum antibiotic therapy should be initiated pending culture and sensitivity results. Empiric antibiotic choices should be effective against gram-positive and gram-negative organisms and anaerobes. Initial combinations might include ampicillin (22 mg/kg IV q6-8h) and enrofloxacin (15 mg/kg IV q24h in dogs, 5 mg/kg IV q24h in cats); ampicillin and amikacin (15 mg/kg IV q24h); cefazolin (22 mg/kg IV q8h) and amikacin, ampicillin, and ceftazidime (22 mg/kg IV q8h); or clindamycin (10 mg/kg IV q8-12h) and enrofloxacin. Single agents such as ticarcillin/clavulanic acid (50 mg/kg IV q6h), cefoxitin (15 to 30 mg/kg IV q4-6h), or imipenem (5-10 mg/kg IV q6-8h, if bacterial resistance is suspected) could be used initially as well.

Gastrointestinal Protection

Stress-related mucosal disease (SRMD) and subsequent upper GI bleeding are frequently seen in critically ill humans and may also occur in dogs and cats. Clinical signs of hematemesis, hematochezia, or melena should alert the clinician to potentially serious GI hemorrhage. Hypoperfusion of the upper GI mucosa during shock, excessive gastric acid secretion, and impaired mucosal defense mechanisms (mucus secretion, production of growth factors) contribute to the development of SRMD. Furthermore, in humans factors thought to increase the risk of stress-related GI hemorrhage include prolonged mechanical ventilation, extensive burns, hepatic failure, renal failure, coagulopathy, head injuries, multiple trauma, high-dose corticosteroids, nonsteroidal antiinflammatory use, and absence of enteral nutrition. In veterinary patients the incidence of SRMD and clinically significant bleeding is unknown; therefore no guidelines exist for their management.

The initial strategy in critically ill dogs and cats should be to ensure adequate GI perfusion and use early enteral nutrition. High-risk patients should receive pharmacologic prophylaxis for stress-related GI hemorrhage. Based on the currently available evidence in human medicine, it appears that proton pump inhibitors (PPIs) are superior to histamine-2 receptor antagonists (H_2 RAs), which are superior to sucralfate in the prevention of SRMD in adult critical-care patients. Drugs available include omeprazole (PPI) 0.7 to 1 mg/kg PO q24h, pantoprazole (PPI) 0.7 to 1 mg/kg IV q24h, famotidine (H_2 RA) 0.5 to 1 mg/kg IV q12-24h PO, ranitidine (H_2 RA) 0.5 to 4 mg/kg IV q8-12h, and sucralfate (protectant) 0.25 to 1 g/25 kg PO q6-8h. Recent evidence suggests that ranitidine does not decrease acid production in dogs at clinically recommended doses (Bersenas et al., 2005; Cook et al., 1999).

Nutrition

Following initial stabilization of the shock patient, nutritional status should be addressed (see Chapter 3). Adequate nutrition is critical in patients with secondary hypermetabolic states such as sepsis. The enteral route (orally or via nasoesophageal, esophagostomy, gastrostomy, or jejunostomy tube) is preferable if the animal is normotensive, not vomiting, and alert. Parenteral nutrition should be administered if the enteral route is not feasible or contraindicated. If the blood glucose falls below 60 g/dl, 0.5 ml/kg of 50% dextrose should be diluted 1:1 with sterile water and administered IV over 1 to 2 minutes. The fluids should also be supplemented with dextrose as needed (2.5% to 7.5%). Hyperglycemia should be avoided since it has been associated with an increased likelihood of infection and a poorer prognosis.

Novel Therapeutic Strategies

Early Goal-Directed Therapy

For many years it has been recognized that critically ill patients in shock benefit from rapid normalization of abnormal physiologic functions. Many therapeutic strategies have been studied, including reestablishing normal

or even supranormal hemodynamics values to improve the outcome of patients in shock. Although the use of supranormal resuscitation has not proven beneficial, the use of early goal-directed therapy has shown early promise (Kern and Shoemaker, 2002).

Early goal-directed therapy is performed using a series of predefined resuscitation end points to help clinicians resuscitate shock patients as soon as the syndrome is recognized. The aim of these specific end points is to adjust cardiac preload, contractility, and afterload to balance systemic DO_2 with demand. Recently the effect of early goal-directed therapy was evaluated in a prospective, randomized clinical trial that included humans who presented to an emergency room with severe sepsis, septic shock, or sepsis syndrome (Rivers et al., 2001). During the first 6 hours of resuscitation from sepsis-induced hypoperfusion, patients treated with early goal-directed therapy received, in a sequential fashion, fluid resuscitation, vasopressors or dilator agents, red-cell transfusions, and inotropic medications to achieve target levels of central venous pressure (8 to 12 mm Hg), MAP (65 to 90 mm Hg), urine output (at least 0.5 ml/kg of body weight), and ScvO_2 (at least 70%). The other group of patients was treated following a standard therapy at their clinician's discretion. Ultimately patients resuscitated following the early goal-directed therapy plan had higher survival rates. In dogs and cats initiating a similar goal-directed therapy strategy immediately after recognition of a shock syndrome might be beneficial. The use of ScvO_2 monitoring requires further research in veterinary patients.

Relative Adrenal Insufficiency and Use of Steroids

Adrenal insufficiency of critical illness is a well-recognized clinical entity in humans, especially those suffering from sepsis (Cooper and Stewart, 2003). These patients have an increased morbidity and mortality, and the use of physiologic doses of steroids has been shown to improve outcome. Adrenal insufficiency may be secondary to both a decrease in glucocorticoid synthesis (i.e., adrenal insufficiency) and peripheral resistance to glucocorticoids. The diagnosis of the dysfunction relies on assessment of plasma cortisol before and after exogenous corticotropin administration (ACTH stimulation test). A relative adrenal insufficiency may lead to refractory hypotension in shock patients or those with critical illness since steroids normally suppress endogenous vasodilators such as the kallikrein-kinin system, prostacyclin, and nitric oxide. Glucocorticoids also modify the renin-angiotensin system and up-regulate angiotensin II receptors in the vasculature. The use of physiologic doses of steroids in people with refractory hypotension has been well studied (Annane et al., 2004). Critically ill, hypotensive animals may also benefit from physiologic doses of corticosteroids, but further research is required to confirm this. There is controversy regarding the definition of an "adequate" response, the dose of ACTH that should be administered, and the constituents of "replacement" therapy.

In specific situations critically ill patients might benefit from glucocorticoid supplementation. The use of etomidate, which blocks the synthesis of cortisol by reversible inhibition of 11- β -hydroxylase, has an inhibitory effect on adrenal function in critically ill patients and has been associated with an increase in intensive care unit mortality. Patients receiving treatment with corticosteroids for chronic autoimmune or inflammatory diseases and those receiving replacement therapy for hypoadrenocorticism should receive at least physiologic doses of prednisone or dexamethasone during severe illness.

CHAPTER 2

Acute Pain Management

ANDREA L. LOONEY, *Ithaca, New York*

Acute pain has many causes in the small animal population, from vehicular injury, myocardial damage, and musculoskeletal pain, through crush or fall injuries, pancreatitis, and gastric distention, to quill migration, disk injury, and surgical pain. Regardless of injury type, all patients share at least one common pathology—pain. Yet, despite this universality, there appears to be no clear definition across patients. However, we do know that pain induces many physiologic changes that can be acutely detrimental to patients. Among these are increased sympathetic tone, decreased or shunted gastrointestinal (GI) or urinary blood flow, increased blood viscosity, prolonged clotting time, and platelet aggregation. Long-term effects of uncontrolled pain include thromboembolism, ventilation perfusion mismatch, hypoxemia, hypercapnia, increased myocardial work and oxygen consumption, immunosuppression, decreased wound healing, and increased incidence of postsurgical complications. Because pain had surpassed the definition of “detriment” and was becoming recognized as an actual disease, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) announced standards for the regular assessment and management of pain in humans in 1999. The American Animal Hospital Association (AAHA) followed suit in 2003, releasing its Pain Management Standards, established to define pain in both preventable and treatable terms for all small animal patients. The American Pain Society has declared pain the “fifth vital sign.” Accordingly, pain should now be assessed both subjectively and objectively in all veterinary inpatients and outpatients along with other vital parameters. This chapter describes assessment, prevention, and treatment of acute pain in these types of critical patients, cognizant of the emergent nature of many diseases, but striving toward appropriate analgesic management.

PAIN SCORING IN CRITICALLY ILL ANIMALS

The importance of assessing pain is magnified when caring for critically ill, intensive care, acutely traumatized, or surgical patients. Recent literature in emergency medicine suggests that intubated patients near or after code receive inadequate analgesia, likely because of initial misconceptions regarding autonomic signs. In one study intubated patients with hypertension received analgesia; those with hypotension did not. Higher mortality rates were seen in the latter group. Retrospective analysis demonstrated both groups to have shown subtle yet unequivocal behavioral signs of pain. Slower regular administration of analgesics (such as continuous-rate infusions [CRIs]), choosing analgesics with less effect on cardiac output (opioids, nonsteroids), and using simple nonpharmacologic methods

of analgesia (e.g., local blockade, ice) would have been appropriate for these patients despite their hypotension. Animals with systemic inflammatory response syndrome demonstrate pain-induced dysfunction of neurons, vasculature, and many major organs; however, it is particularly difficult even for well-trained nurses, technicians, and clinicians to evaluate these patients regarding pain.

Although acute pain is associated with objective physiologic signs caused by autonomic nervous system activity, the critical or emergent patient may already be experiencing signs such as tachycardia, tachypnea, hypertension, and changes in blood glucose secondary to the surgical, traumatic, or acute-on-chronic conditions. Critical patients also have iatrogenically induced pain from recumbency, venipuncture, bandages or wraps, turning, wound care, catheterization, and suctioning. A recent study undertaken by the American Association of Critical Care Nurses identified positional turning alone as one of the most distressful and painful procedures for recent surgical and traumatized adult humans. Pain in these patients is also amplified as a result of stress, altered sleep, urination and defecation cycles, dietary changes, fear, anxiety, and polypharmacy interactions. Also unfortunate is the fact that pain may be unappreciated in the heavily sedated, paralyzed, or ventilated patient.

Pain scoring is the repetitive process whereby pain status is assessed regularly. More important than choosing one scoring system over another are a few simple facts: (1) serial assessment using both behavioral and physiologic parameters should be used; (2) *pain should be included as a cause of changes in physiologic parameters such as hypercapnia, tachycardia, or changes in blood sugar*; (3) individual behaviors suggestive of pain should override any “scoring”; and (4) the gold standard for determining if pain is the cause of a physiologic or behavioral change is administration of an analgesic drug or technique and observation of its effect. Although recent veterinary literature has stressed attention to both physiologic and behavioral characteristics of pain, it can be challenging to differentiate among the possible etiologies within critical patient populations. As such, behavioral “scoring” often takes precedence; appreciation of both overt and subtle changes in demeanor, responsiveness, and interaction qualities is needed.

In noncomatose patients, if objective characteristics of pain are not convincing, the patient should be examined for overt behavioral signs of pain. These include panting, shaking, increased respiratory effort, inability to position or move appropriately, pain on palpation near or distant from the wounds, licking, chewing, inappetence, crying, barking, and anxiety. The University of Melbourne Pain Scale and the Glasgow Composite Measures Pain Scale short form offer two well-established pain-scoring systems for

Box 2-1

Simple Pain Scoring System for Noncomatose Patients

Technicians, nursing staff and clinicians ask these seven questions regularly (q2-6h in critical, emergent, or trauma patients). Answers to the questions guide assignment of a “score” based on a scale of 0 to 5, denoted on the line below. Final scoring is subjective but should be relative to the patient’s previous score. Any obvious behavioral or physiologic sign indicative of pain automatically places the score at more than 3.

1. Is the patient’s heart rate and respiratory rate comparable to its preinsult or species normal values?
2. Is the patient willing to get up, walk unassisted, and move without discomfort?
3. Is the patient’s anxiousness, nervousness, aggravation, restlessness controlled?
4. Is the patient vocally quiet at rest and during interaction?
5. Is the patient appetent or interested in eating?
6. Can you palpate on or near the surgical site without the patient reacting?
7. Are your interactions with the patient pleasing to you and to him or her?

More “yes” answers to the above questions indicate lower pain scores (better-controlled pain). More “no” answers to the above questions indicate higher pain scores (animals need additional analgesia).

use in noncomatose patients. My own simple pain-scoring system for noncomatose patients is included in Box 2-1. In addition, within this population, some experts believe anxiety and pain should be scored and treated independently. However, in the *comatose patient* pain is still present but with less overtly apparent expressions. Recent critical-care nursing literature shows that, no matter the level of consciousness, comatose and near-comatose adult patients react to a noxious stimulus by expressing subtle behavioral signs associated with pain. In veterinary patients I recommend close attention to subtle subjective assessment (presence or absence of squinting, grimacing, minor muscle twitching, papillary dilation, sphincter tone changes, body temperature changes, teeth grinding or chattering, ear pinning, photophobia), especially during nursing care or wound palpation, as a means of pain scoring. My pain-scoring system designed for comatose, mentally obtunded, sedated, or ventilated patients is summarized in Box 2-2.

THERAPY

Systemically administered opioids, α -2 adrenergic agonists, local anesthetics, and nonsteroidal antiinflammatory drugs (NSAIDs) are most widely used for acute pain therapy. Recently anticonvulsants, channel blocking agents, reuptake inhibitors, calcitonin, magnesium, β -blockade agents, bisphosphonates, and ketamine (classically labeled adjunctive agents) have been used to treat acute pain. Using a combination of drugs and techniques with different

Box 2-2

Pain Scoring System for Comatose, Heavily Sedated, Anesthetized, Intubated, Paralyzed, or Mechanically Ventilated Patients

Technicians, nursing staff, and clinicians ask these questions regularly (q2-6h). Answers to the questions guide assignment of a “score” based on a scale of 0 to 5, denoted on the line below. Final scoring is subjective but should be relative to the patient’s previous score. Any obvious behavioral or physiologic sign indicative of pain automatically places the score at more than 3.

1. Is the patient’s heart rate and respiratory rate comparable to its preinsult or species normal values?
2. Has pain been ruled out as a differential for vital parameter changes? (Test dose of fentanyl 3 to 5 mcg/kg and midazolam 0.1 to 0.3 mg/kg can be used to determine if pain is cause of parameter changes.)
3. Is the patient quiet at rest? (Listen for subtle moaning, crying, whining, or grunting. Mechanical ventilation may need to be silenced momentarily to perceive subtle vocalizations, especially in cats.)
4. Subtle muscle twitches or contractions; tremors; or fasciculations, including grimacing, squinting, whisker movement, lip, or muzzle changes; are not seen during interaction or observation. Is this true?
5. Overt stiffening of axial or appendicular muscles, splinting, opisthotonos or ventriflextion - is not seen during interaction. Is this true?
6. Palpation at or near the insult, injury, or surgical site is not painful. Is this true?
7. Defecation or urination is not seen during interaction. Is this true?
8. Urinary or anal sphincter tone does not change with interaction near or distant to the insult or injury site. Is this true?
9. There is an *absence* of teeth chattering, grinding, or temporomandibular and oropharyngeal activity during interaction or observation. Is this true?
10. There is no lacrimation or salivation seen with interaction or palpation of surgical/injury site. Is this true?
11. Increased or abdominal effort on inspiration is not observed, and respirations appear easy and uninhibited, not impeding mechanical ventilation if present. Is this true?

More “yes” answers to the above questions indicate lower pain scores (better-controlled pain). More “no” answers to the above questions indicate higher pain scores (animals need additional analgesia).

pain control mechanisms (known as *multimodal therapy*) improves analgesia and allows for a lower dosage of each single drug (supraadditive or synergistic effect), minimizing adverse drug effects of individual drugs. Ideally both nonpharmacologic and pharmacologic analgesia therapies should be directed at any or all of the four major steps in the nociceptive pathway: transduction at the periphery, transmission along neuronal axons to the dorsal horn of the spinal cord (peripheral nerves) or brainstem (cranial nerves), modulation at the dorsal horn of the spinal cord, and perception at the cerebrum.

Major Pharmacologic Agents

Opioid Analgesics

Opioids that interact with the mu receptor (fentanyl, morphine, oxymorphone, and hydromorphone) are noted for their ability to produce profound analgesia with mild if any sedation and little cardiovascular change. These are considered major analgesics and constitute the first line of pain control for critical, emergent, and acutely ill patients. Fentanyl, hydromorphone, and oxymorphone are my choices for acute pain management. Slow (over 2- to 5-minute) boluses constitute first-line analgesia, especially for the critical or acutely injured patient; CRIs of morphine, remifentanyl, and fentanyl or, alternatively, intermittent injections of hydromorphone or oxymorphone allow continued analgesia in the same patient. Remifentanyl is a potent analgesic requiring close attention to ventilatory status, but it is extremely useful because of its short half-life and metabolism via plasma esterases. Butorphanol, a mixed agonist-antagonist opioid, and buprenorphine, a partial agonist opioid, are *not* candidates for acute pain therapy because of their short-lived analgesic effect, profound sedative effect (masking pain), potent receptor adhesion, and ability to even potentiate (versus treat) pain.

A common “cocktail” used to treat patients in acute pain is the combination of an opioid (hydromorphone or oxymorphone 0.1 mg/kg, or fentanyl 3 to 5 mcg/kg) with a benzodiazepine (midazolam or diazepam 0.3 mg/kg) intravenously. Ketamine can also be added to these agents to provide analgesia along with immobilization. In most patients (except the animal with hypertension, hyperthyroidism, or overt cardiac failure), doses of 1 to 2 mg/kg of ketamine are usually well tolerated as an addition to the above cocktail. Transdermal opioids such as the fentanyl patch can be used as part of multimodal management. However, systemic uptake is very unreliable, especially in patients with circulatory and heat discrepancies. Furthermore, these agents are not capable of producing the immediate and profound analgesia necessary in traumatic, acute, or emergent situations. Transdermal systems are best used out of the emergent period or as adjunct methods of analgesia combined with more potent narcotics (intravenous [IV] opioids) and other agents initially. Fentanyl patches are best used in chronic, low-level pain states.

Of the major side effects seen with opioids, foremost is dose-related respiratory depression reflecting diminished response to carbon dioxide levels. Nausea, vomiting, and dysphoria are commonly observed in animals that are not in pain. The vast majority of injured patients either do not show or can tolerate these side effects. Outside of mild bradycardia, narcotics produce few if any clinically significant cardiovascular effects in dogs and cats. Bradycardia alone should not be contraindications to opioid use, especially in acute, emergent, or critical patients. Because opioids increase intracranial and intraocular pressure, they should be used more cautiously in patients with severe cranial trauma and/or ocular lesions. However, even in these patients opioids can be used with slow initial IV boluses, titratable CRI or intermittent low-dose intramuscular (IM) or partial IV/IM dosing. These approaches minimize vomiting and potent respiratory depression in ocular and head trauma patients. Most opioids depress

the cough reflex via a central mechanism; this may be an advantage in intubated patients but may occasionally predispose to aspiration pneumonia.

Certain of the opioids are capable of causing intense histamine release (morphine/meperidine), which precludes them from being administered intravenously, at least in high dosages. Hydromorphone may cause panting but, more important, seems to cause consistent vomiting in small animals and frequent, sometimes dangerous, hyperthermia in cats. Repetitive use of opioids as solo analgesics often results in two complications: urinary retention and GI ileus (with inappetence, nausea, and constipation). Treatment of these complications involves multimodal therapy (using another form of analgesic concomitantly with the opioid), using a more titratable opioid (fentanyl or remifentanyl), using antiemetic and prokinetic drugs, and instituting minor physical therapy (massage, passive range of motion [PROM], walking) if the patient's injury affords. Although analgesics are given intravenously whenever possible to ensure distribution of the drug and to avoid the need for painful IM injections, use of split IV and IM/ subcutaneous dosing at regular intervals (q6-8h) can reduce GI and urinary side effects, dysphoria, and agitation/panting, especially in feline patients.

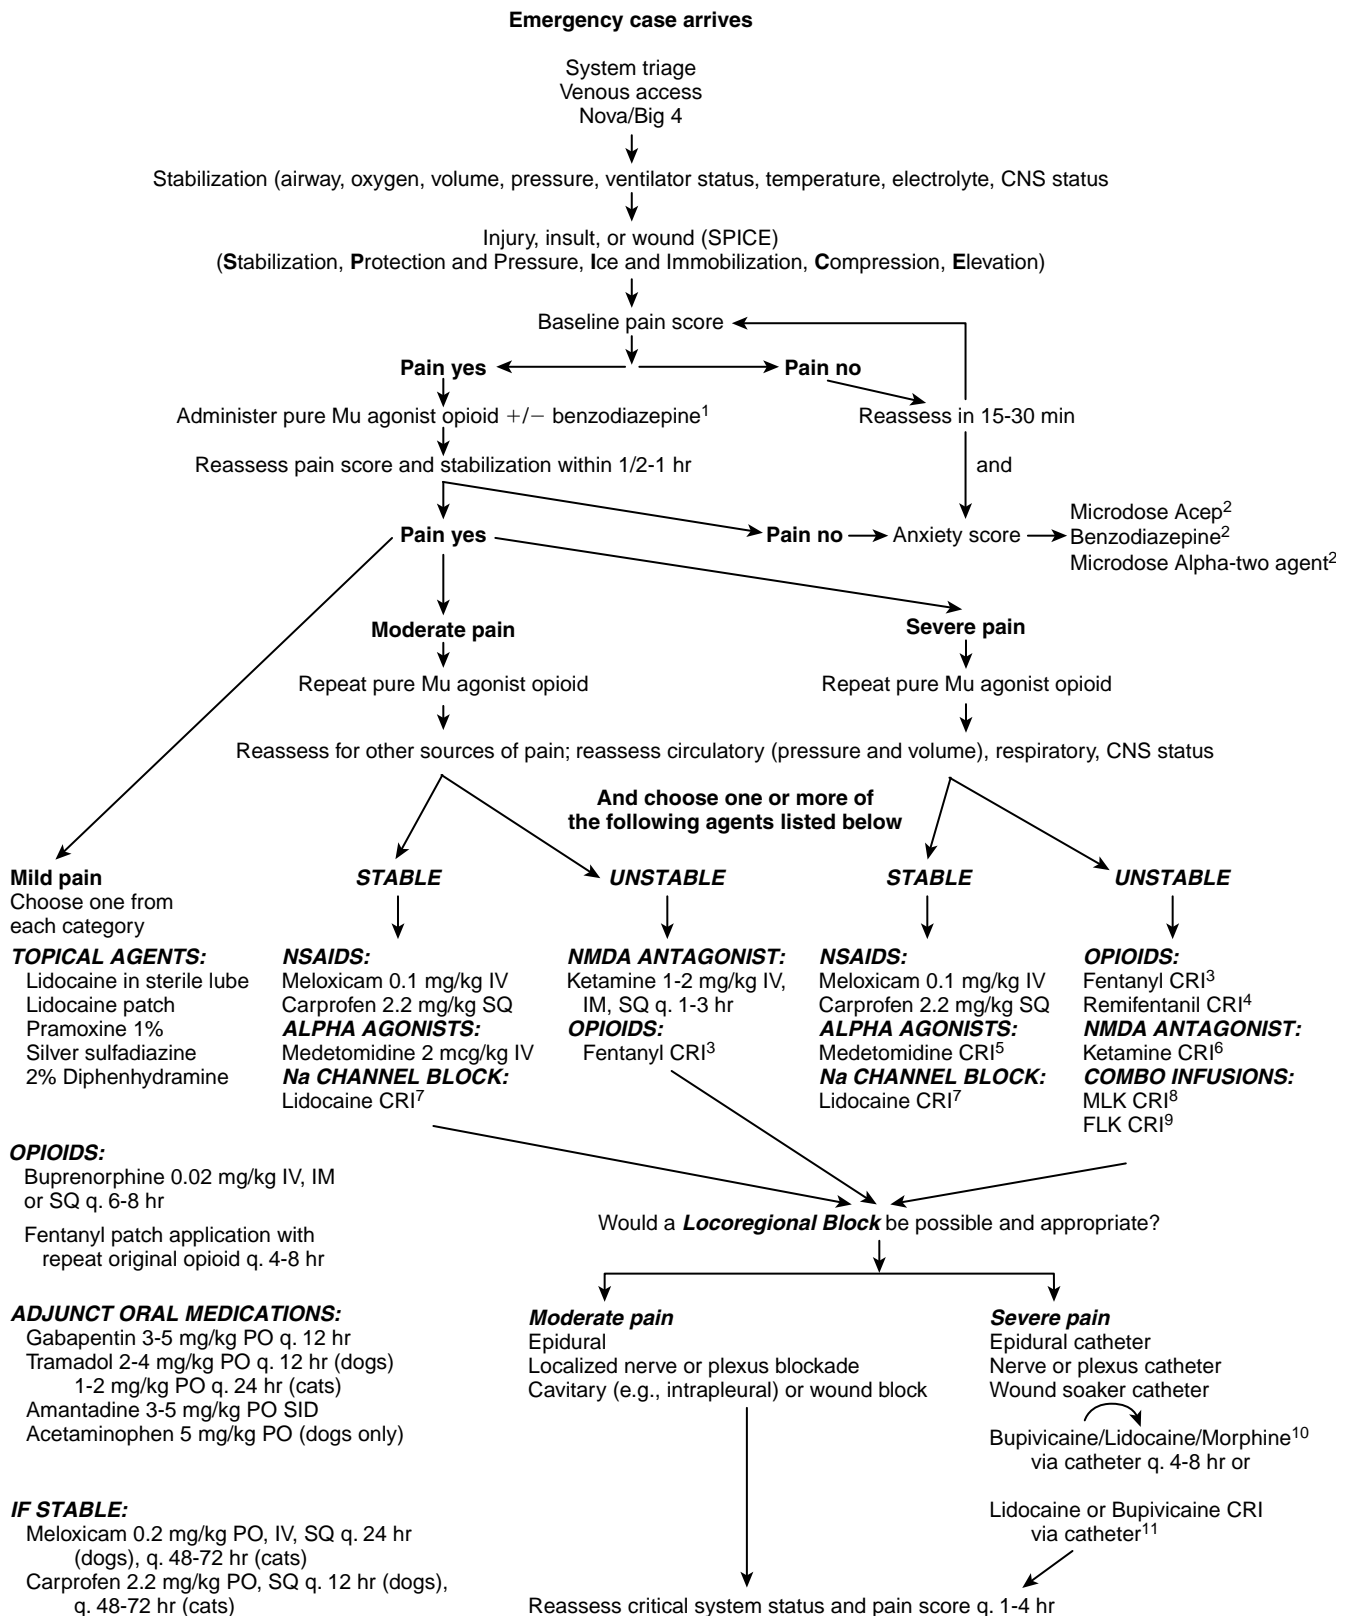

A key characteristic of opioids that makes them desirable for use in emergency and critical-care situations is their reversibility. All reversal agents such as naloxone and naltrexone should be administered slowly (over 10 minutes) if given intravenously, in diluted form, and to effect. Many of the opiate reversal agents are stimulatory to the central nervous and cardiovascular systems if given quickly. Hypertension, tachycardias, and seizures may be seen with rapid administration. Antagonism of narcotics is very short-lived. As such it is common for these drugs to wane and for renarcotization to occur. All opioids are controlled substances; their strict regulations for ordering, storage, and record keeping may make them problematic. Yet these drugs are essential for pain control and constitute the most effective drug therapies for acute, critical, emergent, and perioperative pain (Table 2-1). Fig. 2-1 illustrates a reasonable first approach for using opioids for acute pain management in emergent patients.

Table 2-1

Opioids for Critical Patient Management

Opioid	Dosage
Fentanyl	0.005-0.02 mg/kg q2h IM, IV, SQ or in CRI 0.1-0.2 mcg/kg/min
Remifentanyl	1-3 mcg/kg IV, followed by 3-10 mcg/kg/h CRI because of extremely short initial bolus half-life
Morphine	0.1-0.5 mg/kg q4-8h IM, SQ in dogs; 0.1-0.3 mg/kg q12-24h in cats; or in CRI 0.02-0.1 mg/kg/hr in both species
Oxymorphone	0.02-0.1 mg/kg q4-12h IV, IM, SQ
Hydromorphone	0.02-0.2 mg/kg q4-12 h IV, IM, SQ
Meperidine	5-10 mg/kg IM, SC q2-4h

CRI, Continuous-rate infusion; IM, intramuscularly; IV, intravenously; SQ, subcutaneously.

α -2 Agonist Analgesics

This class of drug warrants special attention because of its potent analgesic power at doses that are also capable of inducing profound sedation and cardiovascular changes. α -2 Agonists have quickly attained “sedative analgesic” status in veterinary medicine. Used at ultra-low doses (often called microdoses), these are useful adjunct analgesics, especially when combined with narcotics. Medetomidine has proven to be equal to or better as a short-term analgesic than buprenorphine, hydromorphone, or oxymorphone for control of pain in dogs. Sedative and analgesic effects are the result of activation of presynaptic and postsynaptic α -2 receptors, which decrease pain-related nor-epinephrine transmission.

Most notable of α -2 agonist side effects are changes in heart rate and rhythm. Atrioventricular blocks, bradyarrhythmia, and sinus bradycardia are caused by vasoconstriction, decreased sympathetic output, and reflex increases in parasympathetic tone. These changes are even noticeable after microdosing. Arterial blood pressure usually increases transiently and then decreases to normal or mildly decreased levels. Cardiac output decreases drastically as a result of lowered cardiac contractile force and stroke volume, which precludes the use of α -2 agents as first-line analgesics for acute pain, even though myocardial circulation may actually improve in some species. Since α -2 receptors modulate the release of insulin by the pancreas, hyperglycemia and resultant glycosuria are produced. Diuresis is also caused by an antiadrenocorticotrophic hormone effect on the renal tubules.

The coadministration of an opioid with medetomidine appears quite useful for enhanced sedation and analgesia well beyond that achieved with either drug alone. *Medetomidine and dexmedetomidine should be used after volume and pressure stabilization, perisurgically, and always as microdose adjunct agents in the acute pain care setting (see Fig 2-1).* Especially beneficial is the microdose of medetomidine (1 to 3 mcg/kg intravenously or intramuscularly, canine and feline) used to supplement pain relief provided by morphine, hydromorphone, or oxymorphone. Medetomidine brings a great benefit not appreciable with narcotic analgesics (i.e., stress reduction). Sympathetic

stimulation is useful in the very peracute initial stages of injury but quickly (within 12 hours) becomes detrimental. Since systemic effects of the stress response add not only to difficulty in controlling pain via any method but also to increased chances of chronic pain states through central hypersensitization and “wind-up,” blunting of this stress response can be extremely useful in *poststabilization* multimodal pain therapy. An added benefit of the α -2 agonists is the potential for rapid reversal in emergency or even titratable reversal with antagonist drugs such as atipamezole. Unlike reversal of the opioids, reversal of an α -2 agent is both complete and long lasting.

Contraindications for α -2 agonists include untreated shock, hypotension, hypertension, overt bleeding, clinical bradyarrhythmias, Addison's disease, and syncope. I use medetomidine as an adjunct agent with the following generalities: longer than 12 to 24 hours after initial insult (animal stabilized), in microdose form (Table 2-2) alternating between intermittent doses of narcotic or as a CRI, and, finally, only in patients capable of tolerating mild-to-moderate reduction of cardiac output. These drugs should not be used in patients experiencing shock or cardiovascular collapse.

Table 2-2

Commonly Used α -2 Agonists

α -2 Agonist	Dosage
Dexmedetomidine	Dog: 0.001-0.003 mg/kg q4-6 h SQ, IM, IV Cat: 0.003-0.01 mg/kg q4-6 h SQ, IM, IV Both species: continuous-rate infusion of 0.2-2 mcg/kg/hr
Medetomidine	Dog: 0.001-0.005 mg/kg q 4-6 hr SQ, IM, IV Cat: 0.003-0.01 mg/kg q.4-6 hr SQ, IM, IV Both species: continuous rate infusion of 0.2-2 mcg/kg/hr

Fig. 2-1 Flow chart for acute pain management in the emergent patient. ¹Pure Mu agonists: Hydromorphone 0.05 to 0.1 mg/kg IV, IM, SQ; oxymorphone 0.1 to 0.2 mg/kg IV, IM, SQ; morphine 0.1 to 0.5 mg/kg IM; fentanyl 3 to 10 mcg/kg IV, IM, SQ.

Benzodiazepines: Midazolam 0.3 to 0.5 mg/kg IV, IM, SQ; diazepam 0.2 to 0.5 mg/kg IV.

SQ administration should be avoided in emergent, acute, and critical-care patients.

²Microdose anxiolytics: Acepromazine 0.01 to 0.05 mg/kg IV, IM, SQ not to exceed 0.3 mg in cats and 1 mg in dogs; diazepam and midazolam at doses noted in footnote 1; medetomidine or dexmedetomidine 1 to 3 mcg/kg IV, IM, SQ.

³Fentanyl continuous-rate infusion (CRI): 0.02 to 0.2 mcg/kg/min.

⁴Remifentanyl CRI: 1 to 2 mcg/kg/hr; monitor ventilatory status cautiously in patients on remifentanyl CRI. (MM Flores, personal communication.)

⁵Medetomidine CRI: 0.02 to 2 mcg/kg/hr.

⁶Ketamine CRI: 5 to 20 mcg/kg/min.

⁷Lidocaine CRI: dog: 50 to 100 mcg/kg/min.

⁸MLK CRI: see Table 2-4, drug calculator located at http://www.vasg.org/constant_rate_infusions.htm, or morphine 0.1 mg/kg/hr, lidocaine 50 mcg/kg/min, ketamine 10 mcg/kg/min (for cats delete lidocaine). (Courtesy of Dr. Robert Stein, DVM, DAAPM and Dr. David Thompson, DVM.)

⁹FLK CRI: Fentanyl 0.1 mcg/kg/min; lidocaine 50 mcg/kg/min; ketamine 10 mcg/kg/min (for cats, delete lidocaine).

¹⁰Intermittent injections via epidural catheter: 0.1 mg/kg morphine in 0.2 mg/kg bupivacaine with or without saline not to exceed 0.2 ml/kg total volume; intermittent injections via peripheral nerve catheters: 0.1 to 0.2 mg/kg bupivacaine with or without 0.2 to 1 mg/kg lidocaine with or without 0.01 mg/kg morphine with or without saline to expand for plexus coverage.

¹¹CRIs via epidural catheter 0.05 mg/kg/hr bupivacaine or ropivacaine in 0.05 mg/kg/hr morphine.

Nonsteroidal Antiinflammatory Drugs

NSAIDs, classically used to treat chronic pain and inflammation, have taken on a new role in treatment of perioperative and acute pain. Potent oral and parenteral forms of these drugs compare favorably with opioids for treatment of acute inflammation and pain. Although multiple modes of action are proposed, most NSAIDs act by inhibiting the enzyme system cyclooxygenase (COX), an enzyme found in at least three forms (-1, -2, -3), prostanoids such as thromboxane, prostacyclin, prostaglandin (PG)_{E₂}, PGF₂, and PGD₂. These prostanoids serve as mediators of inflammation and amplifiers of nociceptive input and transmission. They also affect homeostatic functions such as platelet adhesion, gastric epithelium turnover, renal vasodilation, and bronchodilation. Lipoxygenase (LOX), another enzyme inhibited by some NSAIDs, also acts on arachidonic acid to form eicosatetraenoic acids and leukotrienes. All NSAIDs currently available inhibit COX-2, some avoid inhibition of COX-1 (coxibs), and some also act on LOX (tepoxalin). No single NSAID is substantially more effective than another at treating either acute or chronic pain. COX-1-sparing drugs are not inherently more effective than COX-1-inhibiting drugs.

There are definite and relative contraindications for the use of NSAIDs similar to those directed against the α -2 agents. NSAIDs should not be administered to patients with renal or hepatic insufficiency, dehydration, hypotension, conditions associated with low circulating volume (congestive heart failure, *unregulated anesthesia*, shock), or evidence of ulcerative GI disease. *The vascular volume, tone, and pressure of trauma patients should be completely stabilized before the use of NSAIDs.* Patients receiving concurrent administration of other NSAIDs or corticosteroids or those considered to be cushingoid should not receive parenteral NSAIDs, especially in emergent or acute situations. In addition, NSAIDs should not be used for patients with coagulopathies, particularly those that are caused by platelet number or function defects, or factor deficiencies, or for those with asthma or other bronchial disease.

Where does this leave us in terms of the acutely injured, traumatized, and emergent patient? *The administration of NSAIDs should ONLY be considered in the well-hydrated, normotensive dog or cat with normal renal or hepatic function, no hemostatic abnormalities, and no concurrent steroid administration.* Furthermore, although opioids and α -2 agonists seem to have an immediate analgesic effect, most NSAIDs take up to 30 minutes for a more subtle effect to be recognized. Thus NSAIDs are not first-line analgesics. However, their importance as part of the multimodal regimen should not be understated. NSAIDs are devoid of many of the side effects of narcotic administration and, compared to corticosteroids, do not suppress the pituitary-adrenal axis. NSAIDs are useful in treating initial tissue injury and suppressing central hypersensitization within the dorsal horn of the spinal cord, a phenomenon known to perpetuate chronic pain states. *These drugs are most useful in cases of orthopedic trauma, skin trauma, and appendicular soft-tissue bruising once stabilization of volume status and assessment of coagulation and renal function have occurred (see Fig 2-1).*

Cats are susceptible to the toxic effects of many NSAIDs because of slow clearance and dose-dependent

Table 2-3

Commonly Used NSAIDs

NSAID	Dosage
Carprofen	Dogs: 2-4 mg/kg PO, IM, IV, SQ q12h; cats: q48-72h
Flunixin meglumine	Dogs and cats: 0.5-1 mg/kg IM, SQ, IV q24-48h for three doses
Ketoprofen	Dogs: 0.5-1 mg/kg PO, IM, IV, SQ q12h; cats: q48-72h
Meloxicam	Dogs: 0.1-0.2 mg/kg q24h; cats 0.1 mg/kg q48-72h

IM, Intramuscularly; IV, intravenously; SQ, subcutaneously; NSAID, nonsteroidal antiinflammatory drug.

elimination secondary to deficient glucuronidation in this species. However, this species difference is not a contraindication to NSAID administration, especially when dealing with acute pain. Simply, both the dose and the dosing interval of most commonly used NSAIDs needs to be altered for these drugs to be used safely in cats.

In both canine and feline patients carprofen and meloxicam have impressive safety records compared to older injectable NSAIDs such as flunixin meglumine and ketoprofen. Nonloading (nonlabel) doses of either agent (Table 2-3) are preferred for acute multimodal therapy. Unlike opioids or α -2 agents, NSAIDs can be continued in the postacute care setting in oral forms.

Local and Regional Techniques of Pain Relief for the Acutely Painful Patient

Local anesthetics may be administered epidurally, intrathoracically, intraperitoneally, and intraarticularly. Lidocaine and bupivacaine are the most commonly administered local anesthetics. Lidocaine provides for quick, short-acting sensory and motor impairment. Bupivacaine provides for later-onset, longer-lasting desensitization without motor impairment. Combinations of the two agents diluted with saline are frequently used to provide for quick-onset analgesia with little motor impairment that lasts between 4 and 6 hours in most patients. Epinephrine-free solutions are recommended, especially in emergent patients. Placement of anesthetic close to nerves, roots, or a plexus is improved with the use of a stimulating nerve locator. Excellent reference to nerve localization for locoregional blockade is provided at www.ivia.org (see references). Cats seem to be more sensitive to the effects of local anesthetics, and the lower ends of most dosage ranges are safest for blockade in this species. Local and regional techniques block the initiation of noxious signals, thereby effectively "preventing" pain from entering the central nervous system. Frequently the neurohormonal response that is stimulated in both pain and stress is blunted as well. Overall the patient has less local and systemic adverse effects of pain, disease processes are minimized, chronic pain states are unlikely, and outcome is improved. Regional techniques are best applied as part of an analgesic regimen that consists of continuous

administration, narcotics (with or without α -agonists), NSAIDs, anxiolytics, and good nursing (see Fig. 2-1). Extended-release (lipid-encapsulated) local anesthetics and opioids, recently available in human pain medicine, may make neuraxial and perineural catheterization unnecessary for long-term regional blockade.

Topical and Infiltrative Blockade

Lidocaine can be added to sterile lubricant in a one-to-one concentration to provide decreased sensation for urinary catheterization, nasal catheter insertion, minor road burn analgesia, and pyotraumatic dermatitis analgesia. Proparacaine is a topical anesthetic useful for corneal or scleral injuries. Local anesthetics can be infiltrated into areas of tissue trauma by using long-term continuous drainage catheters and small portable infusion pumps (www.milaint.com, www.bbraunusa.com). This is a very effective method of providing days of analgesia for massive surgical or traumatic soft-tissue injury. Even without the catheter, incisional or regional soft-tissue blocking using a combination of 1 to 2 mg/kg of lidocaine and 0.5 to 2 mg/kg of bupivacaine diluted with equal volume of saline is effective for infiltrating or "splash" blocking large areas of injury for 3 to 6 hours of analgesia.

Cranial Nerve Blockade

Administration of local anesthetic drugs around the infra-orbital, maxillary, ophthalmic, mental, and alveolar nerves can provide excellent analgesia for dental, orofacial, and ophthalmic trauma and surgical procedures. Each nerve may be desensitized by injecting 0.1 to 0.3 ml of a 2% lidocaine hydrochloride solution and 0.1 to 0.3 ml of a 0.5% bupivacaine solution using a 1.2- to 2.5-cm, 22- to 25-gauge needle. Precise placement (perineurally versus intraneurally with painful neuroma formation common with the latter) is enhanced by using catheters in the foramen versus simple needle administration. Aspiration should always be performed before administration of local agents to rule out intravascular injection.

Intrapleural Blockade

This block is used to provide analgesia for thoracic, lower cervical, cranial abdominal (gastric, hepatic, and pancreatic pain), and diaphragmatic pain. Following aseptic preparation, a small through-the-needle 20- to 22-gauge catheter is placed in the thoracic cavity between the seventh and ninth intercostal space on the midlateral aspect of the thorax. A 0.5- to 1-mg/kg dose of lidocaine and a 0.2- to 0.5-mg/kg dose of bupivacaine dose are aseptically mixed with a volume of saline equal to the volume of bupivacaine and slowly injected over a period of 2 to 5 minutes following aspiration to ensure no intravascular injection. Depending on the lesion, the patient should be positioned to allow the intrapleural infusion to "coat" the area. Most effective is positioning the patient in dorsal recumbency (if injury allows) for several minutes following the block to make sure that local anesthetic occupies the paravertebral gutters and thus the spinal nerve roots. The block should be repeated every 3 hours in dogs and every 8 to 12 hours in cats. The catheter is secured to the skin surface and capped for repetitive administration.

Brachial Plexus Blockade

Administration of local anesthetic around the brachial plexus provides excellent analgesia for forelimb surgery, particularly that distal to the shoulder, and for amputations. Nerve-locator guided techniques are much more accurate and successful than "blind" placement of local anesthetic; however, even the latter is very useful for forelimb injuries. Aseptic preparation is performed over a small area of skin near the point of the shoulder. A 22-gauge, 1.5- to 3-inch spinal needle is inserted medial to the shoulder joint, axial to the lesser tubercle, and advanced caudally, medial to the body of the scapula and toward the costochondral junction of the first rib. Aspiration ensures avascular injection of one third of the volume of local anesthetic mix. The needle is withdrawn slightly and then "fanned" dorsally and ventrally while the remaining solution is injected. Local anesthetic doses are similar to those for intrapleural blockade.

Epidural Anesthesia and Analgesia

Epidural analgesia refers to the injection of an opioid, a phencyclidine, an α -agonist, or an NSAID into the epidural space, whereas *epidural anesthesia* refers to the injection of only local anesthetic. In most patients a combination of the two is used. Epidurals are used for a variety of acute and chronic painful conditions, including surgery or trauma in the pelvis, hind limbs, abdomen, and thorax; amputations of forelimbs and hind limbs; tail or perineal procedures; C-sections; diaphragmatic hernia repairs; pancreatitis; peritonitis; and disk disease. Epidurals performed using opioids or less than 0.25% bupivacaine will not result in hind limb paresis or decreased urinary or anal tone (incontinence). Lidocaine or mepivacaine epidurals are prone to these side effects. Morphine is also one of the most useful opioids for administration in the epidural space because of its slow systemic absorption. Epidural catheters used for the instillation of drugs either through CRI or intermittent injection can be placed in both dogs and cats. Routinely placed through the lumbosacral space, these catheters are used with cocktails, including preservative-free morphine, bupivacaine, medetomidine, and ketamine. This therapy is effective for preventing "wind-up" pain in the peritoneal cavity or the caudal half of the body. Catheters may be maintained for 7 to 14 days if placed aseptically.

The animal is positioned in lateral or sternal recumbency. Sterile preparation is performed over the lumbosacral site. A 20- to 22-gauge 1.5- to 3-inch spinal or epidural needle is advanced through the skin caudal to the spine of L7. The skin penetration site is found by palpating the craniodorsal-most extent of the wings of the ilium bilaterally and drawing an imaginary line between them. The spine of L7 is located immediately behind this line. The site of entry is caudal to the spine. Entry into the epidural space is noted by loss of resistance or observing a drop of saline meniscus being pulled into the space. I prefer bupivacaine 0.1- to 0.3-mg/kg (motor sparing is less than 0.3%) with morphine 0.1 mg/kg for canine patients. This can be diluted to a total volume of 0.1 to 0.15 ml/kg with saline if advancement of the solution into the thoracic area is needed (e.g., thoracotomy, forelimb amputation, diaphragmatic repair). Total volume rarely exceeds 6 ml of

saline, local and opioid combined for *dogs*. This calculation is appropriate for an injection made from the lumbosacral space. Injections made more cranial are reduced in volume by 25% per four to five vertebral bodies.

For *cats* 0.1 mg/kg of morphine is diluted with saline to a total volume of 0.1 to 0.2 ml/kg. Local anesthetic is rarely used because of the propensity to administer it into the subarachnoid space and the increased toxicity potential in this species.

Adjunct Agents and Techniques for Acute Pain

Over the past decade scores of other medications have been used to assist with analgesia in both critical and emergent patients. *Ketamine* was classically considered a dissociative anesthetic, but it also has potent activity as an N-methyl-D-aspartate receptor antagonist. This receptor located in the central nervous system mediates wind-up and central sensitization (a pathway from acute to chronic pain). Blockade of this receptor with microdoses of ketamine results in the ability to provide body surface, somatic, and skin analgesia and to potentially lower doses of opioids and α -agonists. Loading doses of 0.5 to 2 mg/kg are used intravenously initially and continued with CRIs of 2 to 20 mcg/kg/minute. High doses can aggravate, sensitize, or excite the animal in subacute or acute pain. *Tramadol* is an analgesic that possesses both weak mu opioid agonist activity and norepinephrine and serotonin reuptake inhibition. It is useful for mild-to-moderate pain when given orally at doses of 1 to 10 mg/kg PO SID/TID. Cats appear to require only once-a-day dosing, and some are intolerant of doses over 1 to 2 mg/kg/day. Regardless of its affinity for the opioid receptors, its true mechanism of action in companion animals remains largely unknown. *Gabapentin* is a synthetic analog of γ -aminobutyric acid. Originally introduced as an antiepileptic drug, its mechanism of action appears to be modulation of calcium channels. It is among a number of commonly used antiepileptic medications, including pregabalin, carbamazepine, and lamotrigine, that are used to

treat central pain in humans. The rationale is their ability to suppress discharge in pathologically altered neurons. Chronic, burning, neuropathic, and lancinating pain (neuropathic pain) in small animals responds well to 3 to 10 mg/kg PO daily.

Ever since the introduction of local anesthetics, it has been common for clinicians to use drugs that block ion channels control pain. Sodium channels in particular are overexpressed in certain chronically inflamed tissues, particularly nervous tissue. *Lidocaine* is a local anesthetic. When given intravenously at a CRI, it is also effective in the treatment of acute and chronic pain. Side effects are minimal at a rate of 1 to 10 mcg/kg/minute for cats and 50 to 75 mcg/kg/minute in dogs. Pain relief in humans after even a brief IV infusion lasts many hours and sometimes even days. Acute pain is commonly treated in many postsurgical care units with *MLK infusions* (i.e., infusions containing standard amounts and rates of morphine, lidocaine, and ketamine). An example of one such infusion is included in Table 2-4. *Lidocaine patches* have been used for body surface, somatic, and skin pain in both cats and dogs. Patches come in 5% pliable, easily applicable, and moldable form; however, there is some concern about their adhesiveness in small animals, partially on haired skin. They are best applied to appendages and bandaged in place because of their inconsistent adhesive nature. In humans they appear to have a 12-hour life span, and recommendation is for removal before placement of another patch. Blood levels of lidocaine and by-products are not appreciated in either cats or dogs at this time. Likewise, potential for toxicity is low even in cats. Unlike fentanyl, there is little concern for respiratory depression, narcosis, or sedation in the patient or if human exposure occurs. These patches can also be cut and molded to fit an area of pain. I have used them on axial and appendicular structures for soft-tissue and bone pain, burns, road rash, hot spots, sprains, and strains at the following dosing scale (cats: $\frac{1}{4}$ to $\frac{1}{2}$ 5% lidocaine patch q24 h; dogs: $\frac{1}{4}$ to 15% lidocaine patch q12 h). The patch should be removed for a minimum of 12 hours before application

Table 2-4

Morphine, Lidocaine, Ketamine (MLK) Continuous-Rate Infusion Formula for Perisurgical Analgesia

All milliliters of solution noted below are added to a 500-ml bag of balanced isotonic crystalloid fluids (avoid fluids containing lactate) after equal volumes of original solution are removed from the bag. If rate of delivery of final solution is maintenance rate of 60 ml/kg/day or 2.5 ml/kg/hour, the following analgesic rates will be administered: morphine 0.12 mg/kg/hour, lidocaine 50 mcg/kg/minute, and ketamine 10 mcg/kg/minute. If higher rates of intravenous fluids are required, additional nonadditive bags should be used to avoid overadministration or toxicity of constituent analgesics.

For *cats*, avoid lidocaine as part of continuous-rate infusion (CRI). I prefer reduction of each analgesic by half (milligram and milliliter amount) per 24 hours to avoid rebound pain from sudden CRI cessation.

	Concentration (mg/ml)	Milliliters of Analgesic to Add to 500 ml of Crystalloid Fluids	Total Milligrams of Analgesic Used (ml \times concentration)	Total Milliliters of Crystalloid To Remove From 500-ml Bag Before Addition of Analgesics
Morphine	15	1.6	24	32.8 ml total = (1.6 ml + 30 ml + 1.2 ml)
Lidocaine	20	30	600	
Ketamine	100	1.2	120	

of a second patch. *Mexiletine* (4 to 10 mg/kg PO), an oral sodium channel blocker, can be used as an alternative to IV lidocaine for this background provision of analgesia.

Many physical therapy modalities are safe and can provide excellent analgesia for the patient in acute pain. The acronym of *PRICE* (protection, rest, ice, compression, and elevation), which applies to many acute musculoskeletal injuries in human athletes, likely also fits many of our patients in acute pain. Patients in acute pain treated with both immobilization of the injured area (modified Robert Jones's bandage or a temporary splint) and cold compression have greater analgesia and less long-term inflammatory damage. Primary physiologic benefits of cold therapy are decreased local circulation, decreased pain, and decreased tissue extensibility. *Cold therapy compressed onto the injury site is one of the single most frugal means of providing immediate analgesia for acute injury.*

Analgesia goes hand-in-hand with solid nutrition, basic nursing care, attention to anxiety and stress, GI function, movement and motion, bladder and bowel control, and emotional state. Analgesia is also provided by getting an animal to its home environment as soon as possible, allowing family interaction and housemate socialization, and appropriate exercise and stimulation. These simple techniques and care concepts can prevent and reduce pain in the acute and chronically ill patient.

CHAPTER 3

Nutrition in Critical Care

DANIEL L. CHAN, *Hertfordshire, United Kingdom*

RATIONALE FOR NUTRITIONAL SUPPORT IN CRITICAL ILLNESS

Critical illness induces unique metabolic changes in animals that put them at high risk for malnutrition and its deleterious effects. In diseased states the inflammatory response triggers alterations in cytokines and hormone concentrations and shifts metabolism toward a catabolic state. In the absence of adequate food intake, the predominant energy source for the host is derived from accelerated proteolysis. Thus these animals may preserve fat deposits in the face of lean muscle tissue loss. Consequences of malnutrition include negative effects on wound healing, immune function, strength (both skeletal and respiratory), and ultimately overall prognosis. An important point in regard to nutritional support of hospitalized patients is that the immediate goal is not to achieve “weight gain,” per se, which mostly likely reflects shift in water balance, but rather to minimize further loss of lean body mass. Reversal of malnutrition hinges on resolution of the primary underlying disease. Provision of nutritional support is aimed at restoring nutrient deficiencies and providing key substrates for healing and repair.

PATIENT SELECTION

As with any intervention in critically ill animals, nutritional support carries some risk of complications. The risk of complications most likely increases with the severity of the disease, and the clinician must consider many factors in deciding when to institute nutritional support. Of utmost importance, the patient must be cardiovascularly stable before any nutritional support is initiated. With reduced perfusion, processes such as gastrointestinal motility, digestion, and nutrient assimilation are altered; and feeding under such circumstances is likely to result in complications. Other factors that should be addressed before nutritional support include hydration status, electrolytes imbalances, and abnormalities in acid-base status.

In animals that have been stabilized, careful consideration must be given to the appropriate time to start nutritional support. A previously held notion that nutritional support is unnecessary until 10 days of inadequate nutrition have elapsed is certainly outdated and unjustified. Commencing nutritional support within 3 days of hospitalization, even before determining the diagnosis of the underlying disease, is a more appropriate goal in most cases; however, other factors should also be considered and are discussed in the next section.

NUTRITIONAL ASSESSMENT

Proposed indicators of malnutrition in animals include unintentional weight loss (typically greater than 10%), poor hair coat quality, muscle wasting, signs of inadequate wound healing, and hypoalbuminemia. However, these abnormalities are not specific to malnutrition and often occur late in the disease process. A greater emphasis is placed on evaluating overall body condition rather than simply noting body weight. The use of body condition scores (BCSs) has been shown to be reproducible and reliable and a clinically useful measure in nutritional assessment. Fluid shifts may significantly impact body weight, but BCSs are not affected by fluid shifts and therefore are helpful in assessing critically ill animals.

In light of the limitations of assessing nutritional status, it is crucial to identify early risk factors that may predispose patients to malnutrition such as anorexia of greater than 5 days' duration, serious underlying disease (e.g., severe trauma, sepsis, peritonitis, acute pancreatitis), and large protein losses (e.g., protracted diarrhea, draining wounds, or burns). Nutritional assessment also identifies factors that can impact the nutritional plan such as specific electrolyte abnormalities; the presence of hyperglycemia, hypertriglyceridemia, or hyperammonemia; or comorbid illnesses such as renal, cardiac or hepatic disease. In the presence of such abnormalities the nutritional plan should be adjusted accordingly to limit acute exacerbations of any preexisting condition.

Finally, since many of the techniques required for implementation of nutritional support (e.g., placement of most feeding tubes, intravenous catheters for parenteral nutrition) necessitate anesthesia, the patient must be properly evaluated and stabilized before induction of anesthesia. When the patient is deemed too unstable for general anesthesia, temporary measures of nutritional support that do not require anesthesia (e.g., nasoesophageal tube placement, placement of peripheral catheters for partial parenteral nutrition) should be considered.

NUTRITIONAL PLAN

Providing nutrition should occur as soon as it is feasible, with careful consideration for the most appropriate route of nutritional support. Providing nutrition via a functional digestive system is the preferred route of feeding, and particular care should be taken to evaluate if the patient can tolerate enteral feedings. Even if the patient can only tolerate small amounts of enteral nutrition, this route of feeding should be pursued and supplemented with parenteral nutrition (PN) as necessary to meet the patient's nutritional needs. However, if an animal

demonstrates complete intolerance to being fed enterally, some form of PN should be provided. Implementation of the devised nutritional plan should also be gradual, with the goal of reaching target level of nutrient delivery in 48 to 72 hours. Adjustments to the nutritional plan are made on the basis of reassessment and the development of any complications.

CALCULATING NUTRITIONAL REQUIREMENTS

Based on indirect calorimetry studies in dogs, there has been a recent trend of formulating nutritional support simply to meet resting energy requirements (RERs) rather than more generous illness energy requirements (IERs). For many years clinicians used to multiply the RER by an illness factor between 1.1 and 2 to account for purported increases in metabolism associated with different disease states. However, less emphasis is now being placed on these extrapolated factors, and the current recommendation is to use more conservative energy estimates (i.e., start with the animal's RER) to avoid overfeeding and its associated complications. Examples of complications resulting from overfeeding include gastrointestinal intolerance, hepatic dysfunction, and increased carbon dioxide production. Although several formulas are proposed to calculate the RER, a widely used allometric formula can be applied to both dogs and cats of all weights. The formula most commonly used by the author is:

$$\text{RER} = 70 \times (\text{current body weight in kilograms})^{0.75}$$

Alternatively, for animals weighing between 3 and 25 kg, the following may be used:

$$\text{RER} = (30 \times \text{current body weight in kilograms}) + 70$$

In regard to protein requirements, hospitalized dogs should be supported with 4 to 6 g of protein per 100 kcal (15% to 25% of total energy requirements), whereas cats are usually supported with 6 or more g of protein per 100 kcal (25% to 35% of total energy requirements). In most cases estimation of protein requirements is based on clinical judgment and recognition that in certain disease states (e.g., peritonitis and draining wounds) protein requirements are markedly increased.

PARENTERAL NUTRITIONAL SUPPORT

PN can be delivered via a central vein (total PN [TPN]) or a peripheral vein (peripheral or partial PN [PPN]). TPN commonly refers to providing all of the animal's calorie and protein requirements via the intravenous route. PPN is reserved when the PN supplies only part of the animal's energy, protein, and other nutrient requirements. Because TPN supplies all of the animal's calorie and protein requirements, it is often the modality of choice for animals that cannot tolerate enteral feeding. The disadvantages are that it requires a jugular venous catheter, it is more expensive (typically about 15% to 25% more for a TPN solution compared to a PPN solution for the same-size animal), and it may be associated with more metabolic complications.

PPN may be an alternative to TPN in selected cases, but it is important to be aware that it will not provide all of the animal's requirements. Both TPN and PPN are typically a combination of dextrose, an amino acid solution, and a lipid solution. However, the concentration of some components (i.e., dextrose) varies, depending on whether TPN or PPN is chosen.

Crystalline amino acid solutions are an essential component of PN. The importance of supplying amino acids relates to the maintenance of positive nitrogen balance and repletion of lean body tissue, which may be vital in the recovery of critically ill patients. Supplementation of amino acids may support protein synthesis and spare tissue proteins from being catabolized via gluconeogenesis. The most commonly used amino acid solutions (e.g., Travasol, Clintec Nutrition, Deerfield, IL; Aminosyn II, Abbott Laboratories, North Chicago, IL) contain most of the essential amino acids for dogs and cats, with the exception of taurine. However, as PN is typically not used beyond 10 days, the lack of taurine does not become a problem in most circumstances. Amino acid solutions are available in different concentrations from 4% to 15%, but the most commonly used concentration is 8.5%. Amino acid solutions are also available with and without electrolytes.

Lipid emulsions are the calorically dense component of PN and a source of essential fatty acids. Lipid emulsions are isotonic and available in 10% to 30% solutions (e.g., Intralipid, Clintec Nutrition, Deerfield, IL; Liposyn III, Abbott Laboratories, North Chicago, IL). These commercially available lipid emulsions are made primarily of soybean and safflower oil and provide predominantly long-chain polyunsaturated fatty acids, including linoleic, oleic, palmitic, and stearic acids. The emulsified fat particles are comparable in size to chylomicrons and are removed from the circulation via the action of peripheral lipoprotein lipase. A common misconception exists in regard to the use of lipids in cases of pancreatitis. Although hypertriglyceridemia may be a risk factor for pancreatitis, infusions of lipids have not been shown to increase pancreatic secretion or worsen pancreatitis and therefore are considered safe. However, the one exception is in cases in which serum triglycerides are elevated, indicating a clear failure of triglyceride clearance. Although specific data regarding the maximal safe level of lipid administration in veterinary patients is not available, it would seem prudent to maintain normal serum triglyceride levels in patients receiving PN. Another concern surrounding the use of lipids in PN is their purported immunosuppressive effects via impairment of the reticuloendothelial system, particularly in PN solutions containing a high percentage of lipids. Despite *in vitro* evidence supporting the notion that lipid infusions can also suppress neutrophil and lymphocyte function, studies have not yet correlated lipid use and increased rates of infectious complications.

Electrolytes, vitamins, and trace elements also may be added to the PN formulation. Depending on the hospital and the individual patient, electrolytes can be added to the admixture, included as part of the amino acid solution, or left out altogether and managed separately. As B vitamins are water soluble, they are more likely to become deficient in patients with high-volume diuresis.

(e.g., renal failure, diabetes mellitus), and supplementation could be considered. Since most animals receive PN for only a short duration, fat-soluble vitamins usually are not limiting; therefore supplementation is not usually required. The exception is in obviously malnourished animals in which supplementation may be necessary. Trace elements serve as cofactors in a variety of enzyme systems and can become deficient in malnourished patients as well. In humans receiving PN, zinc, copper, manganese, and chromium are routinely included in the PN admixture. These are sometimes added to PN admixtures for malnourished animals, but their compatibility with the solution must be verified.

The addition of other parenteral medications to the PN admixture is possible; however, their compatibility must also be verified. Drugs that are known to be compatible and sometimes added to PN include heparin, insulin, potassium chloride, and metoclopramide. Although the addition of insulin to PN is often necessary in humans receiving PN, the hyperglycemia seen in veterinary patients with PN usually does not require insulin administration, except for diabetic patients that will require adjustments to their insulin regimen.

PARENTERAL NUTRITION COMPOUNDING

Based on the nutritional assessment and plan, PN can be formulated according to the worksheets found in Boxes 3-1 and 3-2. For TPN (Box 3-1) the first step is the calculation of the patient's RER. Protein requirements (grams of protein required per day) are then calculated, taking into consideration factors such as excessive protein losses or severe hepatic or renal disease. The energy provided from amino acids is accounted for in the energy calculations and subtracted from the daily RER to estimate the total nonprotein calories required. Some protocols do not account for the energy provided by amino acids in the calculations, which may lead to overfeeding in critically ill animals. The nonprotein calories are then usually provided as a 50:50 mixture of lipids and dextrose; however, this ratio can be adjusted in cases of persistent hyperglycemia or hypertriglyceridemia (e.g., a higher proportion of calories would be given from lipids in an animal with hyperglycemia). The calories provided from each component (amino acids, lipids, and dextrose) are then divided by their respective caloric densities, and the exact amounts of each component are added to the PN bags in an aseptic fashion. The amount of TPN delivered often will provide less than the patient's daily fluid requirement. Additional fluids can either be added to the PN bag at the time of compounding or be provided as a separate infusion.

For formulation of PPN, Box 3-2 provides a step-by-step protocol in which patients of various sizes can receive 70% of their RER and approximately meet their daily maintenance fluid requirement. In very small animals (≤ 3 kg), the amount of PPN will exceed the maintenance fluid requirement and increase the risk for fluid overload; thus adjustments may need to be made. Also, in animals requiring conservative fluid administration (e.g., congestive heart failure), these calculations for PPN may provide more fluid than would be safe. This formulation has been

designed so that the proportion of each PN component depends on the weight of the patient, such that a smaller animal (between 3 and 5 kg) receives proportionally more calories from lipids compared to a large dog (>30 kg) that receives more calories in the form of carbohydrates. This allows the resulting formulation to approximate the patient's daily fluid requirement.

Ideally compounding of PN should be done aseptically under a laminar flow hood using a semiautomated, closed-system, PN compounder (e.g., Automix compounder, Clintec Nutrition, Deerfield, IL). If the appropriate facilities and equipment are not available, it may be preferable to have a local human hospital, compounding pharmacy, or human home health care company compound PN solutions using the formulations listed in Boxes 3-1 and 3-2. Alternatively, commercial ready-to-use preparations of glucose or glycerol and amino acids suitable for (peripheral) intravenous administration are available (e.g., ProcalAmine B, Braun Medical Inc., Irvine, CA). Although ready-to-use preparations are convenient, they provide only 30% to 50% of caloric requirements when administered at maintenance fluid rates and as a result should only be used for interim nutritional support or to supplement low-dose enteral feedings.

PARENTERAL NUTRITION ADMINISTRATION

The administration of any PN requires a dedicated catheter used solely for PN administration that is placed using aseptic technique. In most cases this requires placement of additional catheters since PN should not be administered through existing catheters that were placed for reasons other than PN. Long catheters composed of silicone, polyurethane, or tetrafluoroethylene are recommended for use with any type of PN to reduce the risk of thrombophlebitis. Multilumen catheters are often recommended for TPN because they can remain in place for long periods and separate ports can also be used for blood sampling and administration of additional fluids and intravenous medications without the need for separate catheters placed at other sites. Injections into the PN catheter infusion port or administration lines should be strictly prohibited. The high osmolality of TPN solutions (often 1200 mOsm/L) requires its administration through a central venous (jugular) catheter, whereas PPN solutions can be administered through either a jugular catheter or catheters placed in peripheral veins. The concern with high osmolality is that it may increase the incidence of thrombophlebitis, although this has not been well characterized in veterinary patients.

Because of the various metabolic derangements associated with critical illness, TPN should be instituted gradually over 48 hours. Administration of TPN is typically initiated at 50% of the RER on the first day and increased to the targeted amount by the second day. In most cases PPN can be started without gradual increase. It is also important to adjust the rates of other fluids being concurrently administered. For both TPN and PPN, the animal's catheter and infusion lines must be handled aseptically at all times to reduce the risk of PN-related infections.

Box 3-1

Worksheet for Calculating a Total Parenteral Nutrition Formulation

1. Resting energy requirement (RER)

$$70 \times (\text{current body weight in kg})^{0.75} = \text{kcal/day}$$

or for animals 3-25 kg, can also use:

$$30 \times (\text{current body weight in kg}) + 70 = \text{kcal/day RER} = \text{_____ kcal/day}$$

2. Protein requirements

Standard*

Canine

Feline

4-5 g/100 kcal

6 g/100 kcal

Decreased requirements* (hepatic/renal failure)

2-3 g/100 kcal

3-4 g/100 kcal

Increased requirements* (protein-losing conditions)

6 g/100 kcal

6 g/100 kcal

$$(\text{RER} \div 100) \times \text{_____ g/100 kcal} = \text{_____ g of protein required per day (protein req)}$$

3. Volumes of nutrient solutions required each day

a. 8.5% amino acid solution = 0.085 g of protein per milliliter

$$\text{_____ g of protein per day required} \div 0.085 \text{ g/ml} = \text{_____ ml of amino acids per day}$$

b. Nonprotein calories:

The calories supplied by protein (4 kcal/g) are subtracted from the RER to get total nonprotein calories needed:

$$\text{_____ g of protein required per day} \times 4 \text{ kcal/g} = \text{_____ kcal provided by protein}$$

$$\text{RER} - \text{kcal provided by protein} = \text{_____ nonprotein kcal needed per day}$$

c. Nonprotein calories are usually provided as a 50:50 mixture of lipid and dextrose. However, if the patient has a preexisting condition (e.g., diabetes, hypertriglyceridemia), this ratio may need to be adjusted.

*20% lipid solution = 2 kcal/ml

To supply 50% of nonprotein kcal

$$\text{_____ lipid kcal required} \div 2 \text{ kcal/ml} = \text{_____ ml of lipid}$$

*50% dextrose solution = 1.7 kcal/ml

To supply 50% of nonprotein kcal

$$\text{_____ dextrose kcal required} \div 1.7 \text{ kcal/ml} = \text{_____ ml of dextrose}$$

4. Total daily requirements

_____ ml of 8.5% amino acid solution

_____ ml of 20% lipid solution

_____ ml of 50% dextrose solution

_____ ml total volume of total parenteral nutrition solution

5. Administration rate

Day 1: _____ ml/hr

Day 2: _____ ml/hr

Day 3: _____ ml/hr

*Be sure to adjust the patient's other fluids accordingly!

PN should be administered as continuous-rate infusions over 24 hours via fluid infusion pumps. Inadvertent delivery of massive amounts of PN can result if administration is not regulated properly. Once a bag of PN is set up for administration, it is not disconnected from the patient even for walks or diagnostic procedures—the drip regulator is decreased to a slow drip and accompanies the patient throughout the hospital. Administration of PN through a 1.2-micron in-line filter (e.g., 1.2-micron downstream filter, Baxter Healthcare Corp., Deerfield, IL)

is also recommended and is attached at the time of setup. This setup process is performed daily with each new bag of PN. Each bag should only hold 1 day's worth of PN, and the accompanying fluid administration sets and in-line filter are changed at the same time using aseptic technique. PN should be discontinued when the animal resumes consuming an adequate amount of calories of at least 50% of RER. TPN should be discontinued gradually over a 6- to 12-hour period, but PPN can be discontinued without weaning.

Box 3-2

Worksheet for Calculating a Partial Parenteral Nutrition Formulation

1. Resting energy requirement (RER)

$$70 \times (\text{current body weight in kg})^{0.75} = \text{kcal/day}$$

or for animals 3-25 kg, can also use:

$$30 \times (\text{current body weight in kg}) + 70 = \text{kcal/day RER} = \text{_____ kcal/day}$$

2. Partial energy requirement (PER)

Plan to supply 70% of the animal's RER with partial parenteral nutrition (PPN):

$$\text{PER} = \text{RER} \times 0.70 = \text{_____ kcal/day}$$

3. Nutrient composition

(NOTE: For animals ≤ 3 kg, the formulation will provide a fluid rate higher than maintenance fluid requirements. Be sure that the animal can tolerate this volume of fluids)

a. Cats and dogs 3-5 kg:

$$\text{PER} \times 0.20 = \text{_____ kcal/day from carbohydrate}$$

$$\text{PER} \times 0.20 = \text{_____ kcal/day from protein}$$

$$\text{PER} \times 0.60 = \text{_____ kcal/day from lipid}$$

b. Cats and dogs 6-10 kg:

$$\text{PER} \times 0.25 = \text{_____ kcal/day from carbohydrate}$$

$$\text{PER} \times 0.25 = \text{_____ kcal/day from protein}$$

$$\text{PER} \times 0.50 = \text{_____ kcal/day from lipid}$$

c. Dogs 11-30 kg:

$$\text{PER} \times 0.33 = \text{_____ kcal/day from carbohydrate}$$

$$\text{PER} \times 0.33 = \text{_____ kcal/day from protein}$$

$$\text{PER} \times 0.33 = \text{_____ kcal/day from lipid}$$

d. Dogs >30 kg:

$$\text{PER} \times 0.50 = \text{_____ kcal/day from carbohydrate}$$

$$\text{PER} \times 0.25 = \text{_____ kcal/day from protein}$$

$$\text{PER} \times 0.25 = \text{_____ kcal/day from lipid}$$

4. Volumes of nutrient solutions required each day

a. 5% dextrose solution = 0.17 kcal/ml

$$\text{_____ kcal from carbohydrate} \div 0.17 \text{ kcal/ml} = \text{_____ ml of dextrose per day}$$

b. 8.5% amino acid solution = 0.085 g/ml = 0.34 kcal/ml

$$\text{_____ kcal from protein} \div 0.34 \text{ kcal/ml} = \text{_____ ml of amino acids per day}$$

c. 20% lipid solution = 2 kcal/ml

$$\text{_____ kcal from lipid} \div 2 \text{ kcal/ml} = \text{_____ ml of lipid per day}$$

5. Total daily requirements

$$\text{_____ ml of 5\% dextrose solution}$$

$$\text{_____ ml of 8.5\% amino acid solution}$$

$$\text{_____ ml of 20\% lipid solution}$$

$$\text{_____ ml of total volume of PPN solution}$$

6. Administration rate

This formulation provides an approximate maintenance fluid rate.

$$\text{_____ ml/hour of PPN solution}$$

*Be sure to adjust the patient's other fluids accordingly!

ENTERAL NUTRITIONAL SUPPORT

In critically ill animals with a functional gastrointestinal tract, the use of feeding tubes is the standard mode of nutritional support. As discussed previously, a key decision is determining whether the patient can undergo general anesthesia for placement of feeding tubes. In animals with surgical disease requiring laparotomy, placement of gastrostomy or jejunostomy feeding tubes should receive particular consideration. Feeding tubes commonly used in critically ill animals are nasoesophageal, esophagostomy, gastrostomy, and jejunostomy. The decision to choose one tube over another is based on the anticipated duration of nutritional support (e.g., days versus months), the need to circumvent certain segments of the gastrointestinal tract (e.g., oropharyngeal injury, esophagitis, pancreatitis), clinician experience, and suitability of patient to withstand anesthesia (very critical animals may only tolerate placement of nasoesophageal feeding tubes). More in-depth information of the various feeding tube options is discussed elsewhere in this text (see Chapter 136).

MONITORING FOR COMPLICATIONS

Because the development of complications in critically ill animals can have serious consequences, an important aspect of nutritional support involves close monitoring. With implementation of enteral nutrition, possible complications include vomiting, diarrhea, fluid overload, electrolyte imbalances, feeding tube malfunction, and infectious complications associated with insertion sites of feeding tubes. Metabolic complications are more common with PN and include the development of hyperglycemia, lipemia, azotemia, hyperammonemia, as well as electrolyte abnormalities. Rarely nutritional support can be associated with severe abnormalities that are sometimes referred to as the refeeding syndrome. Strategies to reduce risk of complications include observing aseptic techniques when placing feeding tubes and intravenous catheters, using conservative estimates of energy requirements (i.e., RER), and careful patient monitoring. Parameters that should be monitored during nutritional support include body temperature; respiratory rate and effort; signs of fluid overload (e.g., chemosis, increased body weight); and serum concentrations of glucose, triglycerides, electrolytes, blood urea nitrogen, and creatinine. Detection of any abnormality should prompt full reassessment.

PHARMACOLOGIC AGENTS IN NUTRITIONAL SUPPORT

Since critically ill animals are often anorexic, there is the temptation to use appetite stimulants to increase food intake. Unfortunately appetite stimulants are generally unreliable and seldom result in adequate food intake in critically ill animals. Pharmacologic stimulation of appetite is often short-lived and only delays true nutritional support. I do not believe that appetite stimulants have a place in the management of hospitalized animals when more effective measures of nutritional support such as placement of feeding tubes are more appropriate. The use of appetite stimulants may be considered in recovering

animals once they are home in their own environment, since ideally the primary reason for loss of appetite should be reversed by time of hospital discharge.

FUTURE DIRECTIONS IN CRITICAL CARE NUTRITION

The current state of veterinary critical-care nutrition revolves around proper recognition of animals in need of nutritional support and implementation of strategies to best provide nutritional therapies. Important areas that need further evaluation in critically ill animals include the optimal composition and caloric target of nutritional support, strategies to minimize complications, and optimize outcome. Recent findings implicating development of hyperglycemia with poor outcome in critically ill humans have led to more vigilant monitoring and stricter control of blood glucose, with obvious implications for nutritional support. Evidence of a similar relationship in dogs and cats is mounting, and ongoing studies are focusing on the possible consequences of hyperglycemia. Until further studies suggest otherwise, efforts to reduce the incidence of hyperglycemia in critically ill animals, especially those receiving nutritional support, should be strongly pursued.

Other exciting areas of clinical nutrition in critically ill humans include the use of special nutrients that possess immunomodulatory properties such as glutamine, arginine, and n-3 fatty acids. In specific populations these agents used singly or in combination have demonstrated promising results, even in severely affected people. However, results have not been consistent, and ongoing trials continue to evaluate their efficacy. To date there is limited information on the use of these nutrients to specifically modulate disease in clinically affected animals. Future studies should focus on whether manipulation of such nutrients offer any benefit in animals.

CHAPTER 4

Antiplatelet and Anticoagulant Therapy

MARILYN DUNN, *Quebec, Canada*

MARJORY B. BROOKS, *Ithaca, New York*

Thrombosis is a major cause of mortality for humans with heart disease, cancer, and stroke—the three most common causes of death in developed countries. Hereditary defects of coagulation inhibitors, referred to as *thrombophilias*, further increase the burden of thrombus formation in humans. Aspirin, heparin, and warfarin have long been the mainstays of antithrombotic therapy in medicine. However, limitations in drug safety and efficacy have prompted the development of new antiplatelet and anticoagulant drugs to supplement or replace traditional drug regimens.

Although hereditary thrombophilias have not been identified in dogs or cats, thrombosis is recognized as a common complication of many acquired diseases, including cardiac, endocrine, inflammatory, and neoplastic disorders. Advances in our understanding of pathologic thrombus formation and recent pharmacokinetic studies of antithrombotic drugs in dogs and cats hold promise for the development of effective thromboprophylactic regimens in small animal practice.

PATHOGENESIS OF THROMBOSIS

Normal hemostasis is maintained through an intricate balance between endogenous anticoagulants and procoagulants. The net effect is preservation of blood flow in the systemic vasculature with localized coagulation at sites of vessel injury. Perturbations in this balance can tip the scales to either excessive bleeding or widespread thrombus formation (hypercoagulability). The concept of *Virchow's triad* (endothelial damage, alterations in blood flow, and hypercoagulability) refers to underlying factors that act singly or in concert to promote thrombus formation in various disease states. The primary disorder influences the site of thrombus formation (arterial or venous vasculature), the composition of the occluding thrombus, and the approach to antithrombotic therapy. The relative proportions of platelets and fibrin in the clot depend on the shear of the injured vessel. Arterial thrombi form under high shear forces and therefore tend to contain a large number of platelets held together by fibrin strands. Venous thrombi form under low shear forces and consist primarily of fibrin and red blood cells. Strategies to inhibit arterial thrombogenesis typically include the use of antiplatelet drugs, whereas anticoagulants are the mainstay of venous thromboprophylaxis. Ultimately clinical trials are required for optimization of drug dosages and drug combinations for specific thrombotic syndromes.

DIAGNOSIS OF HYPERCOAGULABILITY

Identification of hypercoagulability is a great challenge in veterinary medicine. Routine coagulation tests (prothrombin time [PT], partial thromboplastin time [PTT]) are designed to detect “hypocoagulability,” and assays that measure consumption of anticoagulant proteins and fibrinogen are generally insensitive indicators of subclinical thrombosis. Nevertheless, low plasma antithrombin (AT) activity and high fibrin degradation product, D-dimer, and fibrinogen levels provide laboratory evidence of hypercoagulability. In human studies platelet hyperaggregability and expression of platelet activation markers such as P-selectin have been observed in patients with thrombotic tendencies. Thromboelastography (TEG) is a technique that depicts global hemostasis, beginning with clot formation and ending with clot lysis. Characteristic changes in the TEG profile have been associated with hypercoagulability in people. Evaluation of platelet function and TEG has been done and may prove useful in veterinary practice to detect hypercoagulability and monitor antiplatelet and anticoagulant therapy.

ANTIPLATELET DRUGS

Antiplatelet agents act through inhibition of platelet activation pathways or interference with membrane receptors. The three classes of antiplatelet drugs in current use include nonsteroidal antiinflammatory drugs (NSAIDs) (cyclooxygenase inhibitors), thienopyridines (adenosine diphosphate [ADP] receptor antagonists), and glycoprotein (GP)IIb/IIIa blockers (fibrinogen receptor antagonists).

Nonsteroidal Antiinflammatory Drugs

Aspirin is recommended as the first-line antiplatelet drug in human cardiac syndromes and is the most commonly used antiplatelet drug in veterinary medicine. Aspirin causes irreversible acetylation of the platelet cyclooxygenase active site, leading to decreased thromboxane A₂ synthesis. The effects of aspirin are permanent and last for the life span of the platelet (7 to 10 days). In contrast, other NSAIDs compete with arachidonic acid binding to cyclooxygenase, thereby producing a reversible inhibition. Despite its widespread use, prospective studies confirming the clinical efficacy of aspirin in thrombosis prevention in dogs and cats are lacking. In a retrospective study of immune-mediated

hemolytic anemia (IMHA) in dogs, improved survival was attributed in part to low-dose (0.5 mg/kg PO) aspirin administration (Weinkle et al., 2005). A retrospective study of cats with arterial thromboembolism demonstrated no difference in survival for cats treated with low-dose aspirin (5 mg/cat PO every 72h) compared with standard-dose aspirin (≥ 40 mg/cat q24-72h) or warfarin (Smith et al., 2003). Cats receiving standard-dose aspirin had a greater risk of gastrointestinal hemorrhage than those receiving the low dose. Given the retrospective nature of the study, it was not possible to determine whether aspirin prophylaxis could prevent initial thrombus formation.

Thienopyridines

Thienopyridines irreversibly inhibit the binding of ADP to specific platelet ADP receptors (P2Y₁₂). ADP receptor blockade impairs platelet release reaction and ADP-mediated activation of GPIIb/IIIa, thereby reducing primary and secondary aggregation response. These drugs must be metabolized by hepatic cytochrome p450, with platelet inhibition occurring by 3 days after initiation of therapy. Clopidogrel (Plavix, Sanofi-Aventis) and ticlopidine (Ticlid, Novopharm) are the two available thienopyridines. These drugs have been evaluated in healthy cats. Ticlopidine effectively decreased platelet aggregation but was associated with unacceptable gastrointestinal side effects. Clopidogrel at dosages of 18.75 to 75 mg PO every 24 hours was well tolerated and resulted in significant antiplatelet effects (Hogan et al., 2004). An ongoing prospective study (FATCAT) comparing clopidogrel to aspirin may help define the more effective agent for secondary prevention of feline aortic thrombosis. Plavix has been used empirically in dogs at a dosage of 1 to 2 mg/kg daily.

Glycoprotein IIb/IIIa Antagonists

Activation of GPIIb/IIIa is the final common pathway of platelet aggregation, regardless of the initiating stimulus. Therefore drugs capable of inhibiting fibrinogen binding to GPIIb/IIIa are potent antiplatelet agents. Three intravenous GPIIb/IIIa antagonist drugs have been developed for clinical use in humans: monoclonal antibodies that bind to the receptor (abciximab [ReoPro], Lilly), and competitive mimetics of fibrinogen (eptifibatide [Integrilin, Schering] and tirofiban [Aggrastat], Merck). In a study of cats with induced arterial injury, abciximab combined with aspirin reduced thrombus formation compared with aspirin alone (Bright, Dowers, and Powers, 2003). Administration of eptifibatide to cats caused circulatory failure and death and therefore is contraindicated. Although dogs have been used in pharmacokinetic and pharmacologic studies of GPIIb/IIIa antagonists, clinical studies have not been performed.

ANTICOAGULANTS

Anticoagulants inhibit the generation of fibrin but do not dissolve preexisting fibrin clots (only thrombolytics can do this). Anticoagulants are used for thromboprophylaxis

in patients considered at risk for a first thrombotic event and to limit fibrin formation in patients with documented thromboembolic disease.

Warfarin

Warfarin (Coumadin, DuPont) is a vitamin-K antagonist that alters the synthesis of vitamin K-dependent clotting proteins (factors II, VII, IX, and X) and the anticoagulants, proteins C and S. Warfarin interferes with hepatic reductase activity, leading to impaired posttranslational carboxylation. The resultant des-carboxy vitamin K-dependent clotting factors have greatly reduced or absent activity. The anticoagulant activity of warfarin is delayed (4 to 5 days) as the newly synthesized inactive clotting proteins gradually replace their functional counterparts. Rapid inhibition of proteins C and S results in a transient period of hypercoagulability in humans, but this phenomenon has not been documented in dogs or cats.

Warfarin is administered orally at an initial dosage of 0.2 mg/kg PO every 12 hours in dogs and 0.1 to 0.2 mg/kg PO every 24 hours in cats (Smith et al., 2000). Close monitoring for dosage adjustment is essential because the anticoagulant effect of warfarin is highly variable from one patient to another. Therapy is monitored based on PT, with a target prolongation to 1.5 times baseline. Because of the variability in PT reagent sensitivity, the World Health Organization has recommended that the PT be expressed as a ratio (International Normalized Ratio [INR]). The INR formula incorporates a factor (ISI) specific to each thromboplastin reagent and is calculated as follows: $INR = (\text{patient PT} / \text{control PT})^{ISI}$. An INR target range of 2 to 3 is considered optimal, without causing excessive bleeding, for most human thrombotic syndromes. INR or PT monitoring is recommended daily for the first week of warfarin therapy, twice weekly for 3 weeks, then once a week for 2 months, and then every 2 months. Dose adjustments should be based on the total weekly dosage. Warfarin is available in 1-mg tablets that should not be divided because of uneven drug distribution throughout the tablet. Since most cats will receive 0.25 to 0.5 mg of warfarin, accurate dosing requires drug compounding. The most common veterinary use for warfarin is thromboprophylaxis for cats with cardiac disease; however, frequent monitoring to ensure optimal dosing is difficult in this patient population. Despite close monitoring, bleeding complications may occur. In one study between 13% and 20% of cats suffered bleeding complications, and 13% of cats had a fatal hemorrhage (Harpster and Baty, 1995). Clients must be informed of the risk of warfarin-induced hemorrhage and the requirement for intensive monitoring before warfarin therapy is initiated.

Heparin

Unfractionated heparin (UH) is a glycosaminoglycan consisting of alternating residues of D-glucosamine and uronic acid. It is a heterogeneous mixture of chains ranging in molecular weight from 5,000 to 30,000 daltons with a mean length of 50 saccharides. Approximately one third of UH molecules possess a pentasaccharide sequence that binds to AT and accelerates its interaction with activated factors IIa (thrombin), IXa, Xa, XIa, and XIIa.

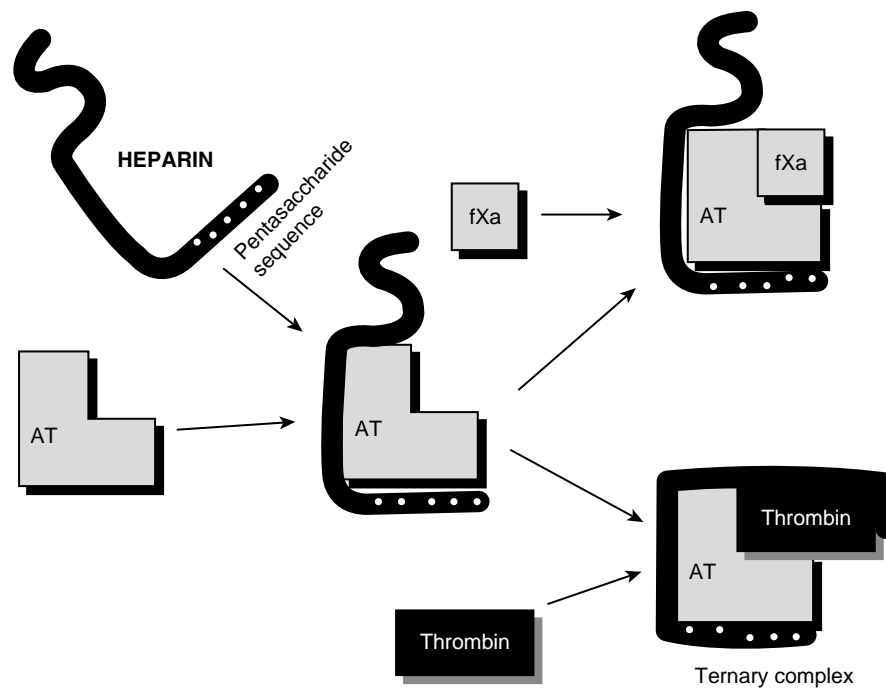

Fig. 4-1 Heparin binds antithrombin through the high-affinity pentasaccharide sequence and inactivates factor Xa. Inactivation of thrombin also occurs but necessitates an additional 13 saccharides. (Modified from Hirsh J, Levine MN: Low-molecular-weight heparin, *Blood* 79:1, 1992.)

Thrombin and factor Xa are most responsive to inhibition by AT. Thrombin inactivation requires formation of a ternary complex involving heparin, AT, and thrombin (Fig. 4-1). Heparin is an indirect anticoagulant, exerting most of its effect through potentiation of AT activity. The drug is administered either intravenously or subcutaneously since it is very poorly absorbed orally.

Heparin has been the anticoagulant of choice for thromboprophylaxis and treatment of thrombosis in human and veterinary medicine. Despite its widespread use, UH has a complex pharmacokinetic profile that produces an unpredictable anticoagulant effect. UH binds to numerous plasma proteins (lipoproteins, von Willebrand's factor, fibrinogen, acute-phase proteins, and AT) and to endothelial cells, macrophages, and platelets. Because of its extensive binding to macrophages and endothelial cells, low-dose subcutaneous UH has poor bioavailability.

For treatment of thrombosis in humans, UH typically is initiated with a bolus dose of 60 to 80 units/kg, followed by infusion of 12 to 15 units/kg/hour. Heparin therapy is then monitored by measurement of the PTT, with dosage adjustment to prolong values to 1.5 to 2.5 times the control value. In addition to PTT, heparin dosage has recently been based on measurement of plasma factor Xa inhibition, to the target range of 0.35 to 0.7 U/ml. Unlike PTT, anti-Xa activity is also suitable for monitoring low-molecular weight heparin (LMWH) therapy.

Empiric UH therapy in veterinary medicine varies widely, encompassing a subcutaneous dosage range of 50 to 500 units/kg every 6 to 12 hours. Pharmacokinetic studies in healthy dogs have shown that dosages of 250 to 500 units/kg will result in target-range anti-Xa activities; however, hematoma formation occurred in some

dogs treated with 500 units/kg SQ at 8-hour intervals (Mischke, Schuttart, and Grebe, 2001). Little clinical data regarding UH monitoring exist in the veterinary literature; however, preliminary reports in IMHA dogs indicate that relatively high dosages (>300 units/kg SQ q6h) will be required to attain target anti-Xa levels (Breuhl, Scott-Moncrieff, and Brooks, 2005).

Low-Molecular Weight Heparin

LMWHs are produced by depolymerization of UH, yielding chains with a mean molecular weight of 5000 daltons and chain lengths of less than 18 saccharides. Like UH, LMWHs possess a pentasaccharide region that binds to AT and accelerates its inhibition of factor Xa. The majority of LMWH molecules are too short to form a ternary complex with thrombin and AT; therefore their ratio of factor Xa to factor IIa inhibitory activity is approximately 4:1. In comparison, UH has a ratio of anti-Xa to anti-IIa activity of 1:1 (Fig 4-2).

LMWHs bind poorly to plasma proteins and cells and undergo first-order renal clearance. In humans the subcutaneous bioavailability of LMWHs approaches 100%, and their elimination half-life allows once- or twice-a-day administration with no need for individual patient monitoring to adjust dosage. Although UH and LMWH demonstrate similar efficacy in most human trials, LMWH is gradually replacing UH because of its more favorable pharmacokinetic properties.

The pharmacokinetics of two LMWHs (dalteparin [Fragmin], Pfizer) and enoxaparin (Lovenox, Sanofi-Aventis) have been investigated in healthy dogs and cats, using anti-Xa activity to monitor anticoagulant effect. In dogs dalteparin has a half-life of 123 minutes, a vol-

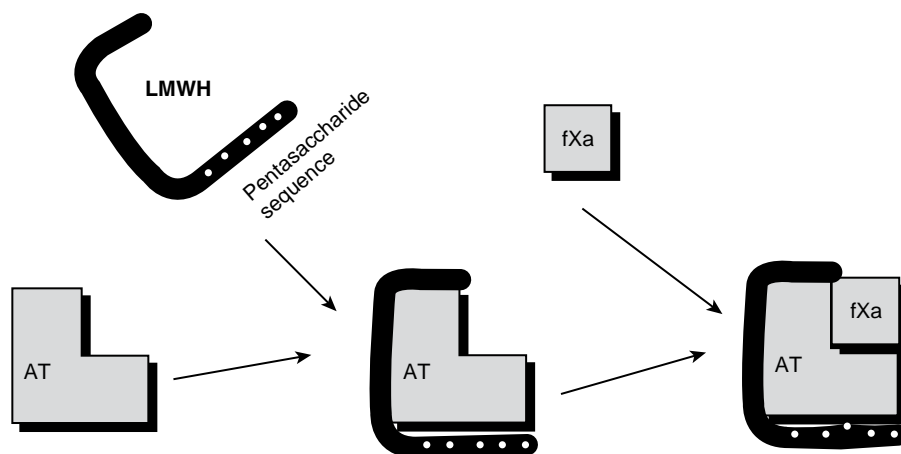

Fig. 4-2 LMWH binds antithrombin through the high-affinity pentasaccharide sequence and inactivates factor Xa. LMWH containing less than 18 saccharides cannot bind to thrombin. (Modified from Hirsh J, Levine MN: Low-molecular-weight heparin, *Blood* 79:1, 1992.)

ume of distribution of 50 to 70 ml/kg of body weight, and an absolute bioavailability of 104% when administered subcutaneously (Grebe et al., 2000). Enoxaparin given to dogs at 0.8 mg/kg every 6 hours produced sustained anti-Xa activity in the range of 0.5 to 2 U/ml (Lunsford et al., 2005). Dalteparin given to dogs at 150 U/kg every 8 hours resulted in anti-Xa activity in the range of 0.2 to 1 U/ml (Mischke et al., 2001). A number of other LMWHs have been used experimentally in dogs (tinzaparin, nadroparin) and appear to have pharmacokinetic properties similar to those in people. In contrast, pharmacokinetic studies of dalteparin and enoxaparin in healthy cats revealed rapid absorption and elimination of the drugs, with peak effects 2 to 3 hours after drug administration. The predicted dosages required to maintain anti-Xa activity equal to or greater than 0.5 U/ml were 150 units/kg every 4 hours for dalteparin and 1.5 mg/kg every 6 hours for enoxaparin (Alwood et al., 2007).

Although anti-Xa activity values are useful for defining UH and LMWH pharmacokinetics and comparing different dosage regimens in clinical trials, the *in vivo* anticoagulant effects of heparin are complex and not limited solely to factor Xa inhibition. A meta-analysis of human trials found that once-daily dosing of LMWHs was as effective in thromboprevention as 12-hour dosing (Dolovich et al., 2000), although once-daily dosing resulted in 12- to 14-hour periods with a subtherapeutic (defined as <0.4 U/ml) anti-Xa level. In humans peak anti-Xa activity appears to correlate more closely to efficacy; however, the relationship between target anti-Xa activity and clinical outcome remains to be fully defined.

Species differences in LMWH pharmacokinetics and anticoagulant effect will complicate the direct extrapolation of data from human trials. In a study of six ill dogs receiving dalteparin at 150 U/kg every 12 hours, results showed that anti-Xa activity peaked predictably 3 hours following administration and fell below therapeutic range 12 hours after the dose (Charland, Thorneloe, and Dunn, 2006). Mestre and colleagues (1985) reported a thrombosis-protective effect in dogs with an anti-Xa activity of 0.55 U/ml. A retrospective study of 57 cats

with cardiac disease treated with 100 units/kg of dalteparin once or twice daily showed that the drug was well tolerated and infrequently caused clinical bleeding (Smith et al., 2004). This study was not designed to test the efficacy of dalteparin, however, and anti-Xa activity was not measured. Ultimately clinical trials to optimize LMWH therapy for specific canine and feline thrombotic disorders will require drug monitoring with anti-Xa activity or other tests such as TEG and defined clinical outcome measures.

New Anticoagulants

Many new anticoagulant drugs are in various stages of development to further improve safety, efficacy, and/or ease of administration beyond that of LMWH. Fondaparinux (Arixtra, GlaxoSmithKline) is an ultra LMWH (consisting only of an AT-binding pentasaccharide sequence) currently approved for treatment and prophylaxis of venous thrombosis.

Direct thrombin inhibitors comprise a new class of anticoagulants that bind to distinct domains on thrombin and block its interaction with substrate. Unlike indirect anticoagulants, the direct thrombin inhibitors neutralize fibrin-bound thrombin. Parenteral drugs in this class include hirudin, bivalirudin, and argatroban. New drugs that inhibit novel procoagulants are in phase I or II trials. These drugs include recombinant TFPI (targeting tissue factor) nNAPC2 (targeting factors X and Xa), and TTP889 (targeting factor IXa).

CHAPTER 5

Cardiopulmonary Cerebral Resuscitation

GRETCHEN L. SCHOEFFLER, *Ithaca, New York*

Cardiopulmonary cerebral resuscitation (CPCR) describes a combination of rescue breathing, chest compressions, and other advanced support measures delivered to patients in cardiopulmonary arrest. The techniques consist of basic life support, advanced life support, and integration of postresuscitation care. In veterinary patients basic life support protocols continue to follow the ABCs (Airway, Breathing, and Circulation). Advanced life support measures include electrocardiographic evaluation of cardiac rhythms, administration of drugs, and defibrillation when necessary. These techniques aim to maintain adequate tissue oxygenation and preserve organ viability during the low-flow "arrest" state to improve the chances of survival, as well as the return of acceptable cerebral and motor functions. Like any other treatment, CPCR *should be administered only if it is expected to confer lasting benefit to the patient*. Patients that suffer cardiopulmonary arrest and have potentially reversible disease are much more likely to survive. Resuscitation of patients with chronic, debilitating illness is more likely to result in prolongation of death. When possible, the decision to not resuscitate should be made in advance, on the merits of each individual case, and in consultation with the owner.

BASIC LIFE SUPPORT

Airway and Breathing

When a patient in cardiopulmonary arrest is identified, it is important to first secure the airway. When orotracheal intubation is impossible, an emergency tracheostomy should be performed. Once an airway is secured, intermittent positive-pressure ventilation using 100% oxygen with either an Ambu bag or anesthesia machine equipped with a rebreathing bag is easily accomplished. It is not necessary to interrupt chest compressions to deliver positive-pressure breaths; breaths and compressions can be delivered simultaneously. It is reasonable to give each breath within a 1-second inspiratory time at a rate of 8 to 10 ventilations per minute. Hyperventilation must be avoided because it is associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion, and in some studies decreased restoration of spontaneous circulation (ROSC). Positive-pressure breaths should achieve a relatively normal chest rise, and, unless lung compliance is very poor, peak airway pressure should not exceed 20 cm of H₂O. Excessively high airway pressures

(greater than 20 cm of H₂O) or inadequate chest wall excursion should lead to a search for potential underlying causes such as tube malposition, occlusion, or pleural space disease. Overaggressive ventilation with high airway pressures can result in iatrogenic pneumothorax, thereby necessitating open-chest resuscitation.

Circulation

The goal of circulatory support during CPR is to generate adequate forward flow of well-oxygenated blood to the heart and brain until spontaneous and effective circulation can be restored. For resuscitative efforts to be effective it is imperative that the technique be optimized in each patient. If the initial technique is not generating an improvement in mucous membrane color or measurable end-tidal carbon dioxide (ETCO₂) levels, an alternate technique should be tried. The compression force or rate could be altered, the position of the animal or the compressor's hands could be changed, or the compressor itself might be relieved. When optimizing the technique in an individual patient, it is not uncommon to try multiple variations.

Closed-Chest Cardiopulmonary Cerebral Resuscitation

The patient is placed in either lateral or dorsal recumbency on a firm flat surface or in a stable V-trough. It is important to stabilize the patient since excessive movement decreases the force of thoracic compressions. If the patient is in lateral recumbency, pressure should be applied over the lateral thoracic wall directly above the heart. If the patient is in dorsal recumbency, the pressure is applied to the caudal aspect of the sternum. The amount of pressure applied should be appropriate to the size of the patient. For example, the resuscitator might place his or her thumb on one side of the chest and the fingers on the other when resuscitating a cat, whereas a two-handed technique would be more appropriate for a large-breed dog. In general, the height of the chest cavity should be reduced by approximately 30% during compression. The resuscitator should maintain a minimum of 100 compressions per minute, with equal time for compression and decompression. Experimental studies have shown that faster compression rates result in improved hemodynamics over slower compression rates. It is also essential that the resuscitator allow for complete recoil of the chest after each compression. Incomplete chest recoil is associated with significantly increased intrathoracic pressure, decreased venous return, and decreased coronary and cerebral perfusion. When feasible, rescuers should frequently alternate compressor duties to ensure that fatigue does not interfere with delivery of high-quality chest compressions or adequate chest recoil. This switch should be made quickly to minimize interruption of cardiac compressions. Interruptions are associated with reduced ROSC and survival, as well as increased postresuscitation myocardial dysfunction.

A variety of alternatives to standard manual closed-chest CPR, including interposed abdominal compressions; active compression-decompression; and the use of impedance threshold valves, mechanical pistons, and load-distributing band devices have been proposed to increase blood flow during closed-chest CPR. Compared

with standard CPR, these techniques and devices typically require more personnel, training, or equipment. The only ancillary procedure readily applicable to the clinical veterinary cardiopulmonary-arrest patient is the interposed abdominal compression technique. When performing interposed abdominal compressions, the abdomen is compressed during the relaxation phase of chest compression. The force of abdominal compression is similar to that needed to palpate the abdominal aortic pulse. Although no significant complications have been reported in experimental models, blunt injuries to parenchymal organs have been witnessed when this technique has been used in dogs. Abdominal compressions may be contraindicated in patients with significant abdominal organomegaly, disease, trauma, or hemorrhage. When applied correctly, interposed abdominal compressions can augment blood pressure, cardiac output, and myocardial and cerebral blood flow. For this reason interposed abdominal compressions might be considered as an adjunct to closed-chest CPR in veterinary patients without evidence of significant intraabdominal disease.

Open-Chest Cardiopulmonary Cerebral Resuscitation

An emergency thoracotomy is indicated in patients who develop cardiopulmonary arrest with penetrating chest or abdominal trauma; chest wall deformity; pericardial tamponade; hemoperitoneum; and significant pleural disease such as pleural effusion, tension pneumothorax, and diaphragmatic hernia. Other recommendations for open-chest CPR include patients that weigh more than 20 kg or arrest during surgery. Open-chest CPR should also be considered in any patient with cardiopulmonary arrest in which external chest compressions with advanced life support fail to restore spontaneous circulation within 5 minutes. Time is the single most important variable in the treatment of cardiopulmonary arrest. Successful resuscitation cannot be expected when instituting open-chest CPR after a prolonged period of ineffective closed-chest CPR. The timing of switching from closed-chest CPR to open-chest CPR will influence the outcome and prognosis of a patient in cardiopulmonary arrest.

Open-chest CPR with internal cardiac massage has been shown to be hemodynamically superior to closed-chest CPR because it increases arterial pressure, cardiac output, coronary perfusion pressure, ROSC, and cerebral blood flow. This technique has additional advantages, including direct visualization of the heart and palpable assessment of diastolic filling. If the heart does not fill rapidly following each individual compression, a lack of venous return is evident, and intravenous fluid bolus or α -adrenergic drug therapy is indicated. Moreover, cardiac fibrillation can be observed directly, and internal defibrillation performed rapidly. In hypovolemic patients or patients with uncontrolled hemorrhage, the descending aorta can be visualized, isolated, and compressed with a finger or cross-clamped with a Penrose drain or a Rumel tourniquet. Occluding the descending aorta directs blood flow to the brain and heart, buying time until adequate volume can be administered or active hemorrhage controlled. If the descending aorta is compressed, it should remain compressed until the resuscitation effort is discontinued. Once the resuscitation effort is discontinued and spontaneous circulation deemed stable, the tourniquet

or compression can be released slowly over 15 to 20 minutes. Experimental studies have demonstrated improved neurologic and cardiovascular outcome and an increase in survival rate when compared to closed-chest CPR.

The most common approach for performing an emergency thoracotomy for resuscitative purposes is a left lateral thoracotomy at the fifth or sixth intercostal space. The intended surgical site should be prepared rapidly by clipping the hair and quickly swabbing the area with antiseptic solution. The incision is performed midway between the ribs down to but not through the pleura. To minimize the risk of lung laceration the pleura should be penetrated between positive-pressure ventilations with a blunt instrument. The incision should be extended with scissors, taking care not to incise the large epaxial muscles dorsally or the internal thoracic artery ventrally. Incising through the large epaxial muscles or the internal thoracic artery (longitudinal to the sternum) can result in significant blood loss and negatively impact the chance for successful resuscitation. Better exposure of the chest cavity and its contents can be achieved by introducing a rib spreader or similar instrument. Once the pericardium is encountered, it is opened ventral to the phrenic nerve, and manual compressions begun. Small hearts may need to be compressed between two fingers; however, large hearts are best compressed between both hands. If the patient is too small to get both hands into the chest cavity, the right hand should be used to compress the heart against the body wall. Care must be taken not to perforate the heart with fingertips or to rotate or displace the heart in a way that may result in occlusion or tearing of the great vessels. The rate of compression should be coordinated to the rate of ventricular filling and, if preload is adequate, should be able to be performed at a minimum rate of 100 compressions per minute. If the open-chest resuscitation effort is successful and spontaneous circulation becomes stable, the thorax should be lavaged with warm, sterile, isotonic saline, and a routine closure achieved. Given the increased chance of survival combined with a very low incidence of complication, it is clear that open-chest CPR should be the resuscitation method of choice in many of our veterinary patients.

ADVANCED LIFE SUPPORT

After initiating effective artificial ventilation and circulation, rescuers should institute advanced life support, including assessment of the electrocardiogram (ECG), establishment of intravenous access, and administration of appropriate therapy. The four most common ECGs associated with cardiopulmonary arrest in small animal patients include pulseless electrical activity, asystole, ventricular fibrillation, and sinus bradycardia. Unfortunately there is no specific treatment for pulseless electrical activity, asystole, or sinus bradycardia; and the only effective method for converting ventricular fibrillation to a perfusing rhythm is the application of electrical defibrillation.

Electrical Defibrillation

The most critical intervention during the first 1 to 2 minutes of ventricular fibrillation is immediate electrical defibrillation. When ventricular fibrillation persists for more than a few minutes, the myocardium becomes depleted of

oxygen and metabolic substrates. In this instance a brief period of compressions can deliver oxygen and energy substrates, increasing the likelihood that a perfusing rhythm will return following shock therapy. It is imperative that basic life support measures continue until the defibrillator is charged and it is time to “clear” the patient for shock delivery. In closed-chest CPR standard handheld defibrillator paddles should be painted with a copious amount of conductive electrode paste and applied to each side of the chest. To maximize current flow through the myocardium, the defibrillator operator should maintain full paddle contact with the skin and reduce the space within the thoracic cavity by applying inward pressure with the paddles. In open-chest CPR special paddles designed for internal defibrillation are wrapped in saline-soaked gauze and held firmly against either side of the heart. Initial energy guidelines for a *monophasic waveform* defibrillator are 1-2 J/kg for internal defibrillation and 8-10 J/kg for external defibrillation. Initial energy guidelines for a *biphasic waveform* defibrillator are 0.3-0.4 J/kg for internal defibrillation and 3-4 J/kg for external defibrillation. Immediately following the shock, basic life support measures are resumed for approximately 2 minutes before reassessing the ECG. The goal is to minimize the time between compressions and shock delivery and between shock delivery and the resumption of compressions. Frequent or long interruptions in compressions are associated with increased postresuscitation myocardial dysfunction and reduced survival rates. This fact suggests that a one-shock strategy may be preferable to the three shocks “stacked” sequence previously recommended for ventricular fibrillation. After successful defibrillation normal electrical impulse generation is established, and myocardial contraction follows. Drug therapy to modulate and support cardiac performance may be necessary during the postresuscitation period since myocardial dysfunction is common and the time to recovery may vary from minutes to hours.

Intravenous and Alternate Routes of Access

A large-bore venous catheter should be placed preferentially in either the external jugular vein (central) or the cephalic vein (peripheral). Catheterization should be accomplished in a vessel cranial to the diaphragm where cephalad blood flow is more pronounced. If percutaneous catheter placement is not rapidly achieved, surgical cutdown of the vessel or intraosseous cannulation should be performed.

Although atropine, epinephrine, vasopressin, naloxone, and lidocaine can be administered by the endotracheal route, plasma concentrations are variable and substantially lower than those achieved when the same drug is given by the intravenous or intraosseous routes. Because the optimal endotracheal dose of most drugs is unknown, these medications are typically administered at 2 to 2.5 times the recommended intravenous dose and diluted in 5 to 10 ml of sterile water to facilitate absorption. Animal studies suggest that high doses of endotracheal epinephrine combined with reduced pulmonary blood flow and absorption can result in the formation of a pulmonary epinephrine depot. During the low-flow state that occurs during CPR the lower plasma epinephrine concentrations achieved when the drug is delivered by the endotracheal route may produce transient β -adrenergic effects. These effects are detrimental, causing hypotension, lower coronary artery perfusion

pressure and flow, and reduced potential for ROSC. On the other hand, if spontaneous circulation does return and cardiac output and pulmonary blood flow are restored, the resulting rapid resorption of high doses of pulmonary epinephrine can result in arterial hypertension, malignant arrhythmias, and ventricular fibrillation. These detrimental results reinforce the fact that, although endotracheal administration of some resuscitation drugs is possible, intravenous or intraosseous drug administration is preferred because it will provide more predictable drug delivery and pharmacologic effect.

Although administering drugs directly into the heart reduces concerns about drug delivery, intracardiac injection may be associated with a number of risks and complications. Blind intracardiac injections should be avoided in closed-chest CPR because of the inaccuracy in aiming at the cavity of the left ventricle and the inevitable interruption of cardiac compressions. Blind intracardiac injections may result in lung, coronary artery, and atrial or ventricular laceration. Accidental intramyocardial deposition of epinephrine may lead to refractory ventricular fibrillation. Many potential complications of blind intracardiac injections may be avoided when the technique is used during open-chest CPR. During open-chest CPR the left ventricle can be visualized, and an accurate injection performed. Regrettably intracardiac injections require an interruption to compressions, and multiple injections cause trauma, which may predispose to ventricular ectopic beats or ventricular fibrillation.

Drug Therapy

During cardiopulmonary arrest basic life support measures and early defibrillation (when indicated) are of primary importance, and drug administration is of secondary importance. Drugs and fluids for cardiopulmonary arrest are categorized as vasopressors, vagolytic agents, antiarrhythmics, other drugs, and fluids.

Vasopressors

Epinephrine remains the vasopressor of choice in patients with cardiopulmonary arrest. Although epinephrine possesses both α and β -adrenergic activity, it is the α -adrenergic (vasoconstrictor) effects that increase coronary and cerebral perfusion pressure and are of primary importance during cardiopulmonary resuscitation. The value and safety of the β -adrenergic effects are controversial because they may increase myocardial work and oxygen demand.

There has been much controversy about and research into the appropriate dose of epinephrine. Two separate doses, high-dose (0.1 to 0.2 mg/kg every 3 to 5 minutes) and low-dose (0.01 to 0.02 mg/kg every 3 to 5 minutes) of intravenous epinephrine are recognized. Current recommendations are to start with the low-dose and titrate up with higher doses if the desired effect is not achieved. The high-dose regimen should be reserved for patients that are refractory to the lower dosages. Many authors recommend ten times this dose when epinephrine is administered via the tracheal tube route. This route should be avoided if at all possible because evidence shows that there may be a paradoxical effect (see the section on endotracheal instillation). In all cases subsequent doses of epinephrine, if needed, should be given every 3 to 5 minutes.

Vasopressin is a nonadrenergic peripheral vasoconstrictor that achieves its effects via direct stimulation of specific vasopressin (V_1) receptors in vascular smooth muscle. Like epinephrine these vasoconstrictor effects increase coronary and cerebral perfusion pressure. However, vasopressin has several advantages over epinephrine and other catecholamines. For example, the vasoconstrictor effects of vasopressin are not blunted in the presence of acidosis; nor is its use associated with increased myocardial work or oxygen demand. Because the effects of vasopressin have not been shown to differ from those of epinephrine in cardiac arrest, it seems reasonable to use one intravenous dose of vasopressin (0.8 U/kg once intravenously) in place of a second dose of epinephrine in the treatment of pulseless arrest.

Vagolytic Agents

Atropine sulfate reverses cholinergic-mediated (parasympathetic) decreases in heart rate, systemic vascular resistance, and blood pressure. The development of sinus bradycardia, pulseless electrical activity, and asystole can be precipitated or exacerbated by excessive vagal (parasympathetic) tone. Atropine is inexpensive and easy to administer and has few side effects; therefore it should be considered for cardiopulmonary-arrest patients exhibiting these rhythms. The full vagolytic dose of atropine (0.04 mg/kg once intravenously) is reserved solely for patients with pulseless electrical activity or asystolic cardiac arrest. This dose of atropine is best avoided in patients with sinus bradycardia because it may result in a sustained tachycardia and increased myocardial oxygen demand. Although low-dose atropine (0.004 to 0.01 mg/kg once intravenously) may be associated with a transient centrally mediated exacerbation of bradycardia, it is the preferred dose in patients with sinus bradycardia.

Antiarrhythmics

Amiodarone is a membrane-stabilizing antiarrhythmic drug that increases the duration of the action potential and refractory period in atrial and ventricular myocardium. Atrioventricular conduction is slowed, and a similar effect is seen with accessory pathways. Although amiodarone (5 mg/kg once intravenously) is associated with a multitude of side effects, when used in conjunction with epinephrine it may prove useful in patients with refractory ventricular fibrillation.

Lidocaine is a class 1B antiarrhythmic that works by inhibiting the fast sodium current and shortening the time to repolarization. Although lidocaine has become the standard intravenous agent for suppression of serious ventricular arrhythmias (2 to 4 mg/kg intravenous bolus followed by continuous-rate infusion (CRI) of 25 to 80 mcg/kg/min intravenously), it has limited use during CPR. Studies have shown that lidocaine can actually raise the defibrillation threshold, making it more difficult to defibrillate a fibrillating heart. As a result, lidocaine is recommended only in postcardiopulmonary-arrest patients that have persistent multifocal or hemodynamically unstable ventricular tachycardia. In addition, it is important to recognize that many patients with ROSC actually have stable idioventricular or ventricular escape rhythms and suppression of those rhythms with lidocaine or other antiarrhythmic agents may prove fatal.

Magnesium is a major intracellular cation and serves as a cofactor in a number of enzymatic reactions. Magnesium treatment (25 to 40 mg/kg or 0.15 to 0.3 mEq/kg slow bolus over 5 to 10 minutes intravenously followed by CRI of 1 to 2 mEq/kg/day intravenously) is indicated in patients with documented hypomagnesemia or with torsades de pointes regardless of cause; however, there are insufficient data to recommend for or against its routine use in cardiac arrest.

Other Drugs

Calcium plays a vital role in the cellular mechanisms underlying myocardial contraction, but there are very few data supporting any beneficial action of therapeutic calcium following most cases of cardiac arrest. High plasma concentration achieved after injection may have detrimental effects on the ischemic myocardium and may impair cerebral recovery. Thus calcium is given during resuscitation only when specifically indicated (e.g., in hyperkalemia, hypocalcemia, and clinically severe overdose of calcium channel blocking drugs). In cardiac arrest calcium gluconate (50 to 150 mg/kg every 15 to 20 minutes intravenously) may be given by rapid intravenous injection. In the presence of a spontaneous circulation it should be given slowly since it can slow the heart rate and precipitate arrhythmias.

Sodium bicarbonate to treat metabolic acidosis during cardiopulmonary arrest is controversial. Cardiopulmonary arrest results in combined respiratory and metabolic acidosis caused by cessation of pulmonary gas exchange and the development of anaerobic cellular metabolism. Data suggest that buffer administration not only lacks benefits but may also be deleterious. Although the routine use of sodium bicarbonate (1 to 2 mEq/kg every 10 to 15 minutes intravenously) in cardiac arrest is not recommended, it has a specific role in hyperkalemia and may be considered in patients with severe preexisting metabolic acidosis or prolonged cardiopulmonary arrest (>15 minutes).

Fluid Therapy

Although there is little evidence supporting intravenous fluid therapy during cardiopulmonary arrest, it has long been advocated as a standard practice in veterinary CPR. Although high fluid rates are appropriate for animals with preexisting hypovolemia or significant ongoing losses, experimental studies indicate that volume loading of euvoletic patients may actually cause a decrease in myocardial and cerebral perfusion. These findings have prompted investigation into small-volume resuscitation protocols using colloidal solutions and hypertonic saline. Although there is not enough evidence to make a standard recommendation, small-volume resuscitation using hypertonic saline may have a positive effect on resuscitation success and recovery after cardiopulmonary arrest.

CPCR MONITORING

Once CPR has been instituted, it becomes necessary to evaluate the effectiveness of the procedure. ECG monitors should be attached to all CPR patients. Unfortunately reading the ECG requires cessation of chest compressions and therefore has an adverse effect on ROSC. To minimize

the interruption of chest compressions, additional methods of monitoring are recommended. Clinicians frequently try to palpate arterial pulses during chest compression. Unfortunately retrograde blood flow into the venous system may produce femoral vein pulsations. Thus generation of a palpable pulse is not a reliable indicator of adequate compression and is not indicative of effective arterial flow. Doppler ultrasonography may be used to assess blood flow, but it is frequently affected by movement artifact. Although assessment of coronary artery perfusion might be helpful, it is technically difficult to measure and not routinely available. During cardiopulmonary arrest pulse oximetry will not function because pulsatile blood flow is inadequate in peripheral tissue beds. Arterial blood gas monitoring enables estimation of the degree of hypoxemia and the adequacy of ventilation during CPR but is not a reliable indicator of the extent of tissue acidosis. In low-flow states such as cardiopulmonary arrest venous blood gas measurements are more reflective of intracellular events in the peripheral tissue beds than are arterial measurements.

ETCO₂ monitoring is a safe and effective noninvasive indicator of cardiac output during CPR. The ETCO₂ reading can be useful in monitoring the progression of CPR because ETCO₂ is linearly related to stroke volume when ventilation is controlled. In low-flow states many of the alveoli are not perfused; thus carbon dioxide (CO₂) is unable to diffuse from the bloodstream into expired gas, and ETCO₂ measurements are low. As blood flow improves, more alveoli are perfused, and more CO₂ is excreted. Success of CPR has been correlated with higher ETCO₂ values in human and porcine models.

CHAPTER 6

Traumatic Brain Injury

DANIEL J. FLETCHER, *Ithaca, New York*
CURTIS W. DEWEY, *Ithaca, New York*

Trauma is a common presenting complaint in small animal veterinary emergency services, and traumatic brain injury (TBI) occurs in a high proportion of these animals. Common causes of TBI in dogs and cats include motor vehicle accidents, animal interactions, falls from heights, blunt trauma, gunshot wounds, and other malicious human behaviors. A global view of the patient is critical when treating TBI, and both extracranial and intracranial priorities must be addressed. Life-threatening extracranial issues such as penetrating thoracic and abdominal wounds or airway obstruction, as well as compromise of oxygenation, ventilation, or volume status must be identified and treated appropriately. Once extracranial factors have been addressed, the focus shifts to intracranial priorities such as maintenance of adequate cerebral perfusion pressure (CPP), oxygen delivery to the brain, and treatment of acute intracranial hypertension.

PATHOPHYSIOLOGY

The pathophysiology of head trauma can be separated into two categories: primary injury and secondary injury. Primary injury is the immediate result of the traumatic event, whereas secondary injury is comprised of a cascade of physiologic and biochemical events that occur in the subsequent hours to days.

Primary Injury

The major types of primary injury that occur after head trauma include concussion, cerebral contusion, cerebral laceration, intraaxial and extraaxial hematomas, and skull fractures. Concussion is characterized by a brief loss of consciousness and is not associated with underlying histopathologic lesions. Hemorrhage into the brain parenchyma and secondary edema comprises cerebral contusion, which can lead to variable severity of clinical signs. Although mild contusion can be difficult to differentiate from concussion, unconsciousness for more than several minutes is most consistent with contusion. Laceration is characterized by physical disruption of the brain parenchyma and can lead to intraaxial hematomas within the brain parenchyma, as well as extraaxial hematomas in the subarachnoid, subdural, and epidural spaces. These space-occupying lesions cause compression of the brain, leading to severe localizing neurologic signs or diffuse dysfunction.

Secondary Injury

TBI triggers a series of events that result in perpetuation of neuronal tissue damage, with both systemic

and intracranial insults occurring independently and in combination. Systemic perfusion derangements contributing to secondary brain injury include hypotension and hypoxemia. Disorders of ventilation contribute to secondary brain injury as well, with hypoventilation causing increased cerebral blood volume (CBV) and hypoxemia, and hyperventilation leading to cerebral vasoconstriction and reduced perfusion. Metabolic abnormalities such as hyperglycemia, hypoglycemia, electrolyte imbalances, and acid-base disturbances further perpetuate secondary brain injury. Intracranial insults include increased intracranial pressure (ICP), compromise of the blood-brain barrier (BBB), mass lesions, cerebral edema, infection, vasospasm, and seizures. All of these factors ultimately lead to neuronal cell death.

Neuronal tissue is especially sensitive to oxidative damage because of its high lipid content. Many mechanisms favor production of reactive oxygen species after TBI, including local hemorrhage, catecholamine production, perfusion deficits, and local acidosis. Local biochemical processes in hypoperfused tissues lead to a milieu primed for generation of reactive oxygen species. Once perfusion is reestablished, these oxidized lipids, proteins, and deoxyribonucleic acids, result in further destruction of neurons.

Damaged neurons inappropriately release excitatory neurotransmitters, causing sodium and calcium influx and depolarization and increasing cellular metabolic activity, depleting adenosine triphosphate stores. Nitric oxide (NO) has been associated with secondary brain injury after trauma, likely because of vasodilatory effects and production of free radicals. Production of other inflammatory mediators has been associated with TBI, leading to secondary injury, including BBB disruption, induction of NO production, mononuclear and polymorphonuclear cell chemotaxis, and activation of the arachidonic acid cascade.

Compromise of Cerebral Perfusion

CPP is the net driving pressure leading to blood flow to the brain. It is defined as the difference between systemic mean arterial pressure (MAP) and ICP.

$$CPP = MAP - ICP$$

Primary and secondary brain injuries leading to increases in ICP, in combination with systemic sequelae of the trauma such as hypovolemia leading to decreases in MAP, ultimately result in worsening of cerebral injury as a result of decreased CPP.

Blood flow to the brain per unit time (cerebral blood flow [CBF]) is a function of CPP and cerebrovascular resistance (CVR). Autoregulatory mechanisms, dependent

largely on local alterations in CVR, allow the normal brain to maintain a constant CBF over a wide range of MAP (50 mm Hg to 150 mm Hg). These autoregulatory mechanisms are commonly compromised in patients with TBI, making them more susceptible to ischemic injury with decreases in MAP.

Acute increases in ICP often trigger the “Cushing’s reflex,” a characteristic combination of systemic hypertension and sinus bradycardia. The initial drop in CPP resulting from increased ICP leads to a dramatic increase of sympathetic tone, causing systemic vasoconstriction and increased cardiac output, ultimately leading to significant increases in MAP. Stimulation of baroreceptors in the aorta and carotid sinus by the increase in MAP triggers a reflex sinus bradycardia. The presence of the Cushing’s reflex in a patient with head trauma is a sign of a potentially life-threatening increase in ICP and should be treated promptly.

ASSESSMENT, DIAGNOSTICS, AND MONITORING

Neurologic Assessment

The modified Glasgow Coma Scale (MGCS) score is a quantitative measure that has been shown to be associated with survival to 48 hours in dogs with TBI and provides a score that can be used to assess both initial neurologic status and progression of signs (Platt, Radaelli, and McDonnell, 2001). This scale incorporates three domains: level of consciousness, posture, and pupillary size/response to light, with a score of 1 to 6 assigned to each domain. The final score ranges from 3 to 18, with lower scores indicating more severe neurologic deficits. The initial neurologic examination should be interpreted in light of the cardiovascular and respiratory systems since shock can have a significant effect on neurologic status.

Initial Diagnostics

Because of the likelihood of multisystemic injury associated with head trauma, initial diagnostics and patient monitoring should focus on a global assessment of patient stability. An initial emergency database should consist of a packed cell volume and total solids to assess for hemorrhage; blood glucose to assess severity of injury; and a blood gas (venous or arterial) to assess perfusion, ventilation, oxygenation, and acid-base status. If possible, samples for a complete blood count and blood chemistry should be obtained before therapy to assess renal and hepatic function and to screen for other systemic disease. In general, occlusion of the jugular vein is contraindicated in patients with TBI because this can lead to increased ICP caused by decreased venous outflow from the brain; therefore samples should be obtained peripherally or via peripherally inserted central catheters.

Imaging of the head is indicated in patients with localizing signs of brain dysfunction, those with moderate-to-severe neurologic deficits that do not respond to aggressive extracranial and intracranial stabilization, and those with progressive neurologic signs. These studies can yield information about targets of potential surgical

intervention such as intraaxial or extraaxial hemorrhage, skull fractures, or cerebrospinal fluid leaks. Skull radiographs have low sensitivity in the assessment of patients with TBI and rarely yield useful diagnostic information. Computed tomography is a sensitive imaging modality that yields excellent detail for assessment of skull fracture, acute hemorrhage, and brain edema.

Monitoring

The overall duration and frequency of episodes of hypoperfusion and tissue oxygenation deficits have been associated with poorer outcomes in people with TBI. Therefore serial monitoring of these parameters is essential for successful management of these patients. Frequent qualitative assessment of tissue perfusion via mucous membrane color; capillary refill time; heart rate and pulse quality; and quantitative assessment of blood pressure, oxygenation, and ventilation is crucial. A minimal MAP of 80 mm Hg should be targeted to decrease the risk of inadequate CPP. If the Doppler technique is used for monitoring, a minimum systolic pressure of 100 mm Hg should be the target. Continuous electrocardiograph monitoring should also be used if possible; if episodes of sinus bradycardia are noted, blood pressure should be assessed for evidence of the Cushing’s reflex, which warrants aggressive therapy directed at lowering ICP.

Techniques have been described for continuous or intermittent direct monitoring of ICP. These techniques are invasive and can lead to complications but yield valuable information for the management of patients with TBI and allow calculation of CPP, the most important of the parameters determining CBF. General guidelines are to maintain ICP below 20 mm Hg and to maintain a CPP of at least 60 mm Hg.

TREATMENT

Treatment priorities for patients with TBI can be divided into two broad categories: extracranial and intracranial. Successful management of patients with TBI depends on addressing both categories.

Extracranial Priorities

Because of the high likelihood of multisystem trauma in patients with TBI, assessment of potential extracranial injuries is an essential part of the initial diagnostic workup. As with any severely injured patient, the basics of Airway, Breathing, and Circulation (i.e., the ABCs) should be evaluated and addressed as necessary. Airway patency should be assessed as soon as possible. Endotracheal intubation or tracheostomy should be considered if complete or partial obstruction is present. Even mild hypercapnia can significantly increase ICP and should not be tolerated. Conversely, hyperventilation leading to hypocapnia can cause cerebral vasoconstriction, decreasing CBF and leading to cerebral ischemia. Therefore manual or mechanical ventilation should be used if necessary to maintain CO₂ at the low end of the normal range (i.e., venous PCO₂, 40 to 45 mm Hg; arterial PCO₂, 35 to 40 mm Hg). The pharynx and larynx should be suctioned as needed to maintain airway patency.

Because hypoxia is common in patients with traumatic injury, supplemental oxygen is indicated in the initial management of all patients with TBI. Patients with pulmonary contusions or other pulmonary parenchymal disease may require mechanical ventilation with positive end-expiratory pressure to maintain adequate oxygenation.

Patients with TBI commonly present in hypovolemic shock, and volume resuscitation goals should be aggressive (MAP of 80 to 100 mm Hg). For patients without electrolyte disturbances normal saline (0.9%) is the best choice of the isotonic crystalloids since it contains the smallest amount of free water and is least likely to contribute to cerebral edema. Synthetic colloids can have a more rapid and long-lasting effect in hydrated patients but are not effective in dehydrated patients. Patients with hypotension caused by hypovolemia and concurrent increased ICP will benefit from a combination of a synthetic colloid (see Chapter 11) (hetastarch or dextran 70) and hyperosmotic (hypertonic saline [HTS]) solution. See Table 6-1 for recommended doses. Patients who do not respond to volume resuscitation require vasopressor support. Because CPP is dependent on MAP, systemic hypotension must not be tolerated.

Intracranial Priorities

The main goals of intracranial stabilization are maintaining adequate cerebral perfusion by controlling ICP, reducing cerebral metabolism, and maintaining adequate systemic blood pressure.

Hyperosmotic Agents

Mannitol is an effective therapy for patients with increased ICP and has been shown to reduce cerebral edema, increase CPP and CBF, and improve neurologic outcome in TBI. It has a rapid onset of action, with clinical improvement occurring within minutes of administration, and these effects can last as long as 1.5 to 6 hours. Mannitol boluses of 0.5 to 1.5 g/kg have been recommended for treatment of increased ICP in dogs and cats. High-dose mannitol boluses (1.4 g/kg versus 0.7 g/kg) were shown to result in improved neurologic outcome in humans in a recent clinical trial (Cruz et al., 2004). Mannitol may increase the permeability of the BBB, an effect that is most pronounced when the BBB is exposed to the drug for prolonged periods of time. The increased permeability can allow mannitol to leak into the brain parenchyma, where it can exacerbate edema. To reduce the risk of this effect, the drug should be administered in repeated boluses rather than as a continuous-rate infusion. The diuretic effect of mannitol can be profound and can cause severe volume depletion. Therefore treatment must be followed with isotonic crystalloid solutions and/or colloids to maintain intravascular volume. In humans mannitol may induce acute renal failure if serum osmolality exceeds 320 mOsm/L; therefore, if possible, serum osmolality should be measured when repeated doses are administered.

HTS is a hyperosmotic solution that may be used as an alternative to mannitol in patients with head injury. Because sodium does not freely cross the intact BBB, HTS

Table 6-1

Drugs and Doses for Patients With Traumatic Brain Injury

Indication	Drug	Dose	Comments
Intracranial Hypertension			
Euvolemic, normotensive, or hypertensive patients	Mannitol 25%	0.5-1.5 g/kg IV over 15 minutes; may repeat	Potent osmotic diuretic. Follow with crystalloids and/or colloids to maintain intravascular volume. Monitor osmolality with repeat dosing.
Hypovolemic patients	HTS (7%)* + dextran-70 or hetastarch	3-5 ml/kg over 15 minutes; may repeat	Contraindicated in hyponatremic patients. Monitor serum sodium concentrations with repeat dosing.
Hypovolemic or euvolemic patients	HTS (7-7.8%)	3-5 ml/kg over 15 minutes; may repeat	Contraindicated in hyponatremic patients. Monitor serum sodium concentrations with repeat dosing. If using 23.4% solution, dilute 1 part HTS with 2 parts 0.9% saline or sterile water.
Anticonvulsant Therapy			
Actively seizing patients	Diazepam or midazolam	0.5 mg/kg IV or rectal bolus; may repeat; 0.2-0.5 mg/kg/hr IV CRI	Do not administer diazepam CRI into peripheral catheters because of the risk of phlebitis.
Prophylaxis for immediate or early seizures, status epilepticus, or cluster seizures	Phenobarbital	16 mg/kg loading dose (divided into 4 doses q2-4h); 2 mg/kg q12h maintenance dosage	Evaluate chemistry for evidence of hepatic dysfunction. Monitor ventilation and blood pressure during loading.
	Potassium bromide	120 mg/kg/day PO for 5 days, then 30 mg/kg/day PO	Sodium bromide can be substituted at the same dose and given IV.

CRI, Continuous-rate infusion; HTS, hypertonic saline; IV, intravenously.

*23.4% HTS: dilute 1 part HTS with 2 parts dextran-70 or hetastarch.

7% to 7.5% HTS: administer separate doses of HTS and dextran-70 or hetastarch (3-5 ml/kg each).

has osmotic effects similar to those of mannitol. Other beneficial effects of HTS include improved hemodynamic status via volume expansion and positive inotropic effects, as well as beneficial vasoregulatory and immunomodulatory effects (Ware et al., 2005). Rebound hypotension is uncommon with HTS administration because, unlike mannitol, sodium is actively resorbed in the kidneys, especially in hypovolemic patients. This makes it preferable to mannitol for treating patients with increased ICP and systemic hypotension caused by hypovolemia. Combining HTS with a synthetic colloid can prolong this volume expansion effect (see Table 6-1). HTS is contraindicated in patients with hyponatremia because it can cause rapid rises in serum sodium concentrations, leading to central pontine myelinolysis and delayed neurologic signs. In euvoletic patients with evidence of intracranial hypertension, both mannitol and HTS can have beneficial effects. If an individual patient is not responding to one drug, the other may yield a beneficial response.

Corticosteroids

Corticosteroids are potent antiinflammatory medications and have been recommended in human and veterinary medicine to treat TBI. A recent clinical trial evaluating over 10,000 human adults with head injury showed that treatment with corticosteroids was associated with worse outcome at 2 weeks and 6 months after injury (Edwards et al., 2005). Because of the lack of evidence of any beneficial effect of corticosteroids after TBI and strong evidence from the human literature showing a detrimental effect on neurologic outcome, corticosteroids should *not* be administered to dogs and cats with TBI.

Furosemide

Furosemide has been used to treat cerebral edema either as a sole agent or in combination with mannitol. This use has been called into question because of the potential for intravascular volume depletion and systemic hypotension, ultimately leading to decreased CPP (Chesnut et al., 1998). It should be reserved for patients in whom it is indicated for other reasons such as those with pulmonary edema or oligoanuric renal failure.

Decreasing Cerebral Blood Volume

Cerebral vasodilation and blood pooling can cause increases in the total volume of blood within the calvaria or in the CBV and can contribute to increased ICP. Several techniques to decrease CBV have been described and have been shown to be effective in people with increased ICP. Hypercapnia caused by hypoventilation can cause cerebral vasodilation and increased CBV. Ventilatory support should be targeted at maintenance of normocapnia (arterial CO_2 of 35 to 40 mm Hg). In cases of severe, acute intracranial hypertension, short-term hyperventilation to an arterial CO_2 of 25 to 35 mm Hg may be used to reduce CBV and ICP. However, chronic hyperventilation is not recommended because the decrease in CBF can lead to cerebral ischemia.

Elevation of the head by 15 to 30 degrees reduces CBV by increasing venous drainage, decreasing ICP, and increasing CPP without deleterious changes in cerebral

oxygenation (Ng and Wong, 2004). It is imperative that occlusion of the jugular veins be avoided by using a slant board to prevent bending the neck. Angles greater than 30 degrees may cause a detrimental decrease in CPP.

Anticonvulsant Therapy

Seizures are common after TBI in humans, with reported incidence rates of up to 54% (Frey, 2003). Posttraumatic seizures are divided into three groups: immediate, occurring within 24 hours of the trauma; early, occurring 24 hours to 7 days after trauma; and late, occurring longer than 7 days after trauma. Several controlled clinical trials have been undertaken in human medicine to investigate the efficacy of prophylactic anticonvulsant therapy after TBI, and a meta-analysis showed an overall reduction in the risk of immediate and early seizures with prophylactic anticonvulsant therapy (Schierhout and Roberts, 1998). Given these data, short-term prophylactic therapy for 7 days after trauma may be indicated in patients with TBI, and anticonvulsant therapy should always be instituted for patients with TBI who develop immediate or early seizures, but there is little evidence to support the use of long-term anticonvulsant therapy to prevent late seizures in these patients. Suggested traditional anticonvulsant drugs and doses are listed in Table 6-1. In addition, several newer anticonvulsant medications have become available in recent years (see Chapter 232). These may prove to be useful alternatives by allowing more thorough neurologic evaluation than traditional anticonvulsants, which have significant sedative effects.

Control of Hyperglycemia

Presence and persistence of hyperglycemia have been associated with worse outcome in numerous clinical studies in human children and adults with TBI. Only one retrospective veterinary study has evaluated the association between hyperglycemia and TBI; and, although an association between admission hyperglycemia and severity of neurologic injury was noted, there was no association between hyperglycemia at admission and survival (Syring, Otto, and Drobatz, 2001). A recent small trial comparing 14 humans with TBI treated with intensive insulin therapy to maintain strict control of blood glucose levels to 33 humans treated with a less strict protocol found significantly lower brain glucose levels in the intensive therapy group but no significant difference in neurologic outcome between the groups (Vespa et al., 2006). This is an active area of research, but, until larger outcome studies are available, there is little evidence to support the use of insulin therapy in patients with TBI.

Decreasing Cerebral Metabolic Rate

TBI can lead to increased cerebral metabolic rate (CMR) and can result in cerebral ischemia and cellular swelling. Therefore therapies targeted at decreasing CMR can reduce secondary brain injury. Induction of barbiturate coma and hypothermia have been used in experimental studies and clinical trials in humans to reduce CMR. Barbiturate coma can effectively decrease ICP via reductions in CMR and has been shown to improve outcome in humans with refractory intracranial hypertension, but hypothermia has not been associated with improved outcome and is not recommended.

Decompressive Craniectomy

Several surgical procedures to address increased ICP have been described in human medicine, including CSF drainage and decompressive craniectomy. The goal of these therapies is to allow expansion of the various intracranial compartments without a subsequent increase in ICP. The use of decompressive craniectomy in human patients with TBI is controversial, and a large-scale, randomized human clinical trial is currently underway (the RESCUEicp Trial), which will compare aggressive medical management with decompressive craniectomy in 500 patients with TBI (Hutchinson et al., 2006). Pending results of this trial, we recommend adoption of current recommendations in the human literature; consider decompressive craniectomy within 12 hours in patients with sustained, increasing ICP that is refractory to medical therapy.

PROGNOSIS

Prognosis following TBI is difficult to predict, and only the MGCS has been shown to be correlated with outcome in small animal patients (Platt et al., 2001). However, our clinical experience would suggest that even patients with severe neurologic deficits at presentation can show marked improvement over the subsequent 24 to 48 hours. Therefore serial neurologic examinations are recommended. Client education is also of paramount importance since persistent or permanent neurologic deficits in patients with TBI are common.

CHAPTER 7

Vascular Access Techniques

JAMES S. WOHL, *Auburn, Alabama*
MARION B. TEFEND, *Auburn, Alabama*

Percutaneous placement of intravascular catheters is the most common method of achieving access to the vasculature for fluid therapy, frequent blood collection, and physiologic monitoring. In emergency patients large-bore peripheral catheters typically are indicated for rapid fluid resuscitation, but they can be problematic because of hypotension, hypovolemia, vascular collapse, trauma, and skin stiffness. Central line catheters are indicated in all severely hypovolemic patients or if central venous pressure monitoring or serial blood sampling is indicated.

In some instances emergency venous or arterial access requires a cutdown procedure. Knowledge of reliable anatomic landmarks and proper surgical technique facilitate successful placement of vascular catheters in the critically ill patient. Cutdowns help ensure that the vessel is cannulated on the first attempt and can allow placement of a larger catheter than what can normally be placed percutaneously. Intraosseous access can be used for all small patients, as well as small birds and reptiles. Intraosseous cannulation (Bonagura, 1992) provides a route for fluid and drug administration but is inadequate for blood collection and cardiovascular monitoring. Percutaneous placement of arterial catheters (Bonagura, 1995) is indicated in patients requiring repeated arterial blood gas analysis or direct arterial blood pressure measurement.

CATHETER SELECTION

Access to the vasculature in the critically ill or traumatized patient allows for the delivery of lifesaving medications, fluid therapy, blood products, or nutrition, all of which can be accomplished through a wide range of specialty catheters. Proper nursing care to patients harboring such devices is critical because any indwelling catheter or tube represents a focus for microbial colonization. Incorrect placement or positioning can cause patient discomfort or compromise. Appropriate selection as to the catheter or tube type, in combination with proper management techniques, is paramount to patient care. Recognizing the advantages and disadvantages of the different types of specialty tubes and the care necessary for maintaining patency of such tubes will benefit patient outcome and prevent unnecessary complications.

Peripheral venous catheters such as the over-the-needle type are the most commonly used method of obtaining vascular access in the small animal patient. Advantages of this catheter type include ease and speed of insertion, low cost, and versatility of access in different anatomic locations. Flow rates are greatly enhanced by placement of

short (2-inch) large-bore (12 to 16 g) catheters placed intravenously. Anatomic location for the peripheral catheter is best used in the cephalic, accessory cephalic, or jugular vein during triage. Other sites of placement of the peripheral over-the-needle catheter can include the saphenous or medial saphenous vein, dorsal common digital vein, or articular or lingual vein. Other uses of the over-the-needle catheter type include pericardiocentesis, abdominocentesis, or thoracocentesis. Another advantage of the over-the-needle catheter is the variety of both the gauge and length available to the practitioner, ranging from 25 g to 12 g and from 2 inches up to 12 inches in length.

Central venous access catheters are advantageous for monitoring central venous pressure, obtaining serial blood sampling with minimal stress to the patient, long-term patient use, and administering of hyperosmolar solutions. The central venous catheter is most commonly placed in the jugular vein but can be readily inserted into the caudal vena cava via the lateral or medial saphenous veins. Other advantages of the central venous catheter are the wide variety of styles available to the veterinarian. Some central venous catheters contain multiple lumens for the simultaneous delivery of incompatible fluid types. Such multilumen catheters are also advantageous to the critical patient in need of fluid therapy, central venous pressure monitoring, intravenous (IV) nutrition, or continuous-rate infusions of medications, all of which can be done through one catheter. Disadvantages of the central venous catheter include a longer placement time, expense, slight patient discomfort during placement, and the relatively narrow diameter of the catheter itself. Since most central venous catheters are long and narrow, rapid fluid administration is not recommended as the primary delivery route, particularly during resuscitation. In addition, since most central venous catheters are placed into a jugular vein, patients with coagulation deficiencies may have complications with association of such devices. Monitoring for extravasations in the central venous catheter is a little more difficult than in the peripheral over-the-needle catheter. Caregivers should monitor the patient for edema of the neck, shoulder, or face; pain with insertion of medication; sluggish flow through the catheter; or inability to aspirate blood back from the catheter.

Long over-the-needle types of central venous catheters are inexpensive and come in a variety of lengths and diameters, ranging from 22 to 16 gauge and from 6 to 12 inches in length. Disadvantages of these catheter types include patient discomfort since they tend to be stiff and are prone to kinking. In addition, most over-the-needle long catheters are made of Vialon or

Teflon material, and should be changed after 5 to 7 days. Central venous catheters placed by the Seldinger technique include the single-to-multilumen devices, which are soft and flexible, made of an antithrombogenic polyurethane material, and can be maintained for longer periods. In addition, some Seldinger central venous catheters are impregnated with antimicrobial solutions that may result in a reduction of catheter-related sepsis. Disadvantages to the Seldinger central venous catheter types are expense, increased risk of local hemorrhage during insertion, and procedure time needed for placement. However, it is our opinion that the advantages of such central venous catheters far outweigh the risks and expense in critical patient use.

Arterial catheters provide an important means by which to monitor a patient's status. Inserted primarily into the dorsal pedal artery, catheterization can also be accomplished in the femoral, brachial, or even the auricular artery. Advantages to arterial catheterization include monitoring patient ventilation, acid-base equilibrium, and direct blood pressure monitoring. Over-the-needle peripheral catheters can be used for such procedures, although arterial catheter kits are now available using the Seldinger technique for ease of placement and long-term use. Percutaneous arterial catheterization is technically difficult because arteries are surrounded by a dense adventitia, are located deeper in fascial tissues than veins, and are not visible through the skin. Arterial catheterization can be further complicated by hypotension or hypovolemia. Medications should not be administered through arterial catheters.

Vascular access ports, or implantable vascular access systems, are subcutaneous delivery systems that allow serial blood sampling or IV administration of medications or fluid. Such devices are advantageous to chronically ill patients that can be treated intermittently on an outpatient basis. Surgically implanted, the catheter and port are subdermal and can be accessed without patient discomfort. Complications associated with such systems are similar to those of other types of IV catheters, including topical infection, sepsis, thrombosis, or extravasations. Nursing care required for vascular ports include daily insertion site inspection, mild antiseptic cleansing, and intermittent heparinized flushes to prevent clogging or occlusion.

CATHETER PLACEMENT TECHNIQUES

Seldinger Technique

Catheters using the Seldinger technique can be placed percutaneously or following exposure of the vessel after mini cutdown or cutdown. Commercially available in single-, double-, or triple- lumen (Arrow, Cook, Beckon-Dickinson, Baxter, or Abbott catheter systems), sizes range from 22 to 16 gauge for peripheral use to 14 gauge to 24 gauge for central use. Lengths range from 16 to 30 cm. Most central catheters are made of polyurethane to help prevent thrombosis and can also be purchased with silver sulfadiazine and chlorhexidine (Arrow International) heparin coating. See Box 7-1 for venous access procedure and Box 7-2 for arterial access procedure.

Box 7-1

Venous Access Procedure

1. Place patient in sternal recumbency with neck hyperextended.
2. Shave a wide area to avoid contamination of insertion site.
3. Perform surgical preparation with solutions containing povidine and isopropyl alcohol.
4. Apply sterile drape to area cranial to insertion site.
5. Premeasure guidewire; tip of guidewire should not exceed apex of heart.
6. *Premeasure central catheter length; tip of catheter should be located in cranial vena cava just outside of the right atrium for central venous pressure monitoring.*
7. Place large-bore, short cephalic catheter.
8. Insert straight end of wire into the vessel via the cephalic catheter to predetermined length.
9. Remove cephalic catheter; ensure that the wire does not inadvertently back out.
10. Insert the plastic dilator into the vessel by placing the wire through it and guiding it to the vessel. Passage of dilator may be facilitated by "tenting" the skin and gently rotating the dilator into the vessel; a cut into the skin with a No. 11 blade next to the wire may ease insertion. Insert one-half length of dilator into the vessel; then remove the dilator.
11. Insert the catheter over the wire and guide it into the vessel to predetermined length. Ensure that the end of the wire is projecting out the distal end of the catheter before advancement; the wire should be held as the catheter is advanced into the vessel. If double-lumen catheters are used, the wire should come out the distal (or colored) port.
12. Remove the wire, leaving the catheter in place.
13. *Aspirate catheter* with small syringe; blood should easily flow into syringe. Flush the catheter with sterile saline and cap.
14. Secure the catheter in place with skin/fascia sutures, apply antiseptic/antibiotic ointment, and place under a sterile dressing. If entire length of catheter is not used, secure excess catheter with plastic catheter holders provided.

VENOUS CUTDOWN TECHNIQUES

Patient Preparation

Except in the most emergent situations, aseptic technique should be maintained during catheter placement. Clipping and surgical preparation of the skin 180 degrees around the cutdown site allow aseptic handling of a limb. Infusion of lidocaine into the skin and subcutis of the proposed cutdown site facilitates placement in awake or sedated patients. Final preparation includes a last surgical scrub and the maintenance of a sterile field containing the necessary instruments, catheters, syringes filled with heparinized saline, injection plugs, stopcocks, and fluid tubing. Sterile latex gloves should be worn when attempting invasive vascular access techniques. Since the focus of the surgeon is on the cutdown site, it is essential that nongloved assistants be present to monitor the patient's vital signs during the procedure.

Box 7-2

Arterial Access Procedure**Materials Needed**

- Clippers
- Surgical scrub
- Suture material
- Heparinized saline flush
- Catheter cap
- Arterial catheter kit or cephalic catheter
- Bandage material
- Saline for infusion if continuous direct blood pressure monitoring is used

Procedure

1. Lay patient in lateral recumbency.
2. Give oxygen if body position compromises respiratory effort.
3. Clip and prep dorsal pedal area (down leg).
4. Palpate pulse with single digit.
5. Stab incision for cutdown at 45-degree angle and at least 1 inch away from palpable pulse.
6. Hold catheter like a dart; insert catheter with bevel up through tunneled area.
7. Insert catheter gently toward pulse (superficial); back out and redirect if no flash.
8. Once flash is obtained, be careful not to move catheter; slide entire length of wire via black tab-handle.
9. "Pop" catheter off the wire and into arterial space.
10. Remove wire and ensure blood flow (should be fast and in spurting or jet motion).
11. Cap and flush catheter; aspirate back to ensure blood flow and reflush.
12. Suture in place (three spots total).
13. Place small amount antibiotic cream over insertion site.
14. Cover with sterile gauze square.
15. Place one layer gauze bandage.
16. Cover catheter with light, stiff bandage and label catheter.

Mini Cutdown

The mini cutdown technique is used for gaining access to the cephalic and lateral saphenous veins. With the bevel facing the operator, a sterile 20- or 22-gauge hypodermic needle is scraped across the skin directly over and parallel to the underlying vein in a proximal-to-distal direction. Tearing skin in this fashion releases skin tension without damaging the underlying vessel. Alternatively a small incision can be made over the vein with a scalpel blade. Although an incision causes a less traumatic defect to the skin, care must be taken to avoid incising the vessel and subcutaneous tissue. A mini cutdown can be used to visualize a collapsed vein but is more commonly used to avoid tissue drag during catheter placement. This technique is most useful in cats with thick skin or when burring of an over-the-needle catheter is prohibiting percutaneous placement. Infusion of lidocaine before mini cutdown is rarely needed, especially in very sick patients.

Surgical Cutdown

Surgical cutdowns can be used over the external jugular, maxillary, cephalic, or lateral saphenous vein. If attempting catheterization of the external jugular vein,

cutdown incisions should be made in the middle-to-cranial portion of the jugular groove. The maxillary vein is a branch of the external jugular vein and is located half the distance between the wing of the atlas and the mandibular salivary gland. For cephalic and lateral saphenous vein cutdowns, incisions are made over their expected locations on the dorsal antebrachium and lateral aspect of the distal tibia, respectively.

The surgical technique is similar for all venous sites. A scalpel blade is used to incise the skin directly over or adjacent to the vein. Either a transverse or a parallel skin incision can be made. Care should be taken to incise only the full thickness of the skin. Blunt dissection (e.g., with mosquito forceps) may be required to visualize the vein as a blue-to-purple tubular structure within the subcutaneous tissue. Minimal dissection is usually required for the placement of an over-the-needle or through-the-needle catheter.

In some instances it may be necessary to isolate the vein. Isolation is accomplished by blunt dissection parallel to the vein. Subcutaneous or adventitial tissue adjacent to the vein is retracted with atraumatic thumb forceps, exposing the vessel. Dissection with the use of sharp-ended scissors is then performed dorsally and ventrally to the vein. Dissecting in a parallel fashion minimizes the chances of rupturing or traumatizing the vessel. After freeing the vein from the subcutaneous tissue, a hemostat is advanced beneath the vein. A silk suture is then clasped by the hemostat and drawn beneath the vessel (Fig. 7-1). The vein can be briefly occluded proximally to enhance filling. The suture can then be used to retract the vein distally and provide adequate tension for the catheterization of the vessel (Fig. 7-2). Alternatively, the vessel may be sacrificed by ligating the vein distally and using the ligature to retract the vessel.

Fig. 7-1 Following isolation of the blood vessel, a hemostat is used to pass a silk suture beneath the vessel. (Art by Lisa Makarchuk; courtesy Auburn University, School of Veterinary Medicine, Auburn, Alabama.)

Fig. 7-2 Retraction of the vessel with a suture applies tension to the vessel, allowing introduction of an over-the-needle catheter. (Art by Lisa Makarchuk; courtesy Auburn University, School of Veterinary Medicine, Auburn, Alabama.)

A second suture is placed beneath the vessel proximally. The vein is then cannulated through a venotomy (or by venipuncture) between the two ligatures. Following catheterization, the proximal suture is ligated, securing the catheter in the vein.

ARTERIAL CUTDOWN TECHNIQUES

The most common site for arterial catheterization is the dorsal metatarsal artery. This artery is most superficial in the proximal metatarsus, medial to the extensor tendons, between the second and third metatarsal bones. A second arterial site is the dorsal pedal artery, which courses medial to the long digital extensor tendon at the level of the proximal tarsus. The femoral artery is less commonly used because of its location and the risk of hemorrhage, the potential danger of puncturing the external iliac artery, and retroperitoneal bleeding.

When a surgical cutdown is performed for arterial catheterization, a technique should be used that preserves vascular sufficiency. An incision is made over the pulsation of the dorsal metatarsal artery in the proximal metatarsus. When isolating the dorsal pedal artery, the incision is made medial and parallel to the long digital extensor in the proximal tarsus. Dissection is performed parallel to the direction of the artery, as described earlier for isolating a vein. The artery is identified as a white tubular structure. A pulse may be palpated, which will distinguish the artery from a nerve or tendon. A silk suture is placed beneath the artery and retracted distally to expose and place tension on the vessel.

An over-the-needle catheter, primed with heparinized saline, is recommended for arterial cannulation. Through-the-needle catheters have a smaller diameter

than the penetrating needle and puncture wound; consequently, leakage of blood can result at the catheter insertion site. A more expensive alternative to an over-the-needle catheter is to use the modified Seldinger technique. This method uses a guidewire over which the catheter is advanced into the artery. A vessel dilator is sometimes used before introducing the catheter. Although the Seldinger technique is thought to be the least traumatic method of catheter placement, arterial cannulation usually can be achieved with over-the-needle catheters.

Topical administration of a few drops of 2% lidocaine onto the artery may prevent arterial spasm and facilitate cannulation. Retracting the artery with silk suture, the needle catheter assembly is inserted into the artery until rapid flow of red arterial blood fills the needle hub. The assembly is then repositioned in line with the artery and advanced an additional few millimeters. The catheter is then advanced off the needle and into the artery. The needle is discarded, and a sterile Luer-Lok injection plug is attached to the catheter. The catheter is flushed with a small volume of heparinized saline. Aspiration of arterial blood through the plugged catheter with a needle and syringe confirms the appropriate placement within the artery. It is important to keep the artery retracted during this procedure to prevent slippage of the artery off the unsecured catheter. In anesthetized patients venous blood may be superoxygenated and have the appearance of arterial blood. Observing pulsatile, rapid blood flow through the open catheter before the insertion of an injection cap indicates that the cannulated vessel is an artery. Blood gas analysis revealing an oxygen tension compatible with arterial blood or connection to a pressure-monitoring system will further confirm proper placement.

Securing the Catheter Without Sacrificing the Artery

The silk retraction suture is removed from beneath the artery. A silk suture with a swaged-on needle is placed above the artery but beneath the hub of the catheter. A finger trap suture is tied around the catheter hub, leaving excess suture on both ends of the second knot. The catheter is allowed to lie in a stationary position, and the remaining length of suture is used to anchor the catheter through the skin, placing minimal tension on the catheter. This method secures the catheter in place without sacrificing the artery and allows withdrawal of the catheter after cutting the anchoring skin suture. One or two interrupted skin sutures may be required proximal to the anchor suture to close the incision site.

Following suturing of the catheter and the incision site, a sterile dressing is applied, and the catheter is bandaged routinely. In awake patients, a soft, padded bandage can be used to inhibit movement of the tarsus. Patency of the catheter is maintained by periodic flushing with small volumes (1 to 2 ml) of heparinized saline injected through the injection cap with a 25-gauge needle or a low-dose saline continuous-rate infusion from a pressurized fluid bag if the catheter is used for continuous blood

pressure monitoring. Manual flushing of larger volumes of fluid with a syringe can cause retrograde blood flow and embolization of particulate matter or air. Most transducer systems used for direct blood pressure monitoring use a squeeze clamp or pigtail flushing device. Attaching a multiport stopcock to the catheter allows connections to a blood pressure monitor and a flushing system and provides an additional site for blood collection. When not in use, stopcock ports should be attached to sterile injection plugs.

Blood Collection

With the stopcock to the designated collection port turned off, the sterile injection plug is removed and protected from contamination by placing it on a sterile gauze square or other sterile field. A sterile 3-ml syringe containing 1 ml of heparinized saline is then attached to the collection port. The stopcock to the flushing system is turned off, and 1 ml of blood is drawn through the catheter into the flush syringe. The stopcock to the patient is turned off, and the sample port and the flush syringe are discarded. The flushed blood mixture should *not* be reinfused following arterial blood collection. A new sterile syringe that has been purged with heparin (if obtaining a blood gas sample) is then attached, the stopcock closed to the flushing system, and the desired amount of blood is drawn *slowly* into the syringe. Rapid, forced withdrawal may injure the artery. After sample collection the stopcock is closed to the sample port, the sample syringe is removed, and the system is flushed for 1 second via the flushing system. To minimize thrombus formation and bacterial contamination, the sample stopcock should be flushed following blood collection. This is achieved by turning the stopcock to the patient off and allowing irrigation solution to flow through the open sample port. Sterile gauze can be used to collect the expelled solution. Following this procedure, the sterile injection plug is returned to the sample port.

Complications and Removal of Arterial Catheters

An arterial catheter should be removed as soon as it is no longer essential for proper patient management. In humans arterial catheters are associated with a higher rate of thrombus formation after a 3- or 4-day dwell time. Evidence of vasculitis, skin discoloration, hemorrhage, or an unexplained fever should prompt evaluation of the catheter site. Cooler-than-normal skin temperature distal to the catheter insertion site may indicate developing catheter-related insufficiency in blood supply and impending ischemic necrosis. Administration of medications through the arterial catheter is not recommended.

When an arterial catheter is removed, all bandage and dressing material should be removed. The anchoring suture is then cut. Firm pressure is applied proximal and distal to the insertion site while the catheter is removed with mild continuous suction applied by a syringe. This method facilitates aspiration of clots surrounding and within the catheter. On catheter removal firm manual pressure is applied over the insertion site for 5 to 10 minutes. After

the application of manual pressure, a pressure dressing is applied for several hours. The insertion site is monitored periodically for internal or external hemorrhage.

MAINTENANCE OF VENOUS AND ARTERIAL CATHETERS

Any indwelling venous or arterial catheter predisposes a patient to the possibility of nosocomial infection. All personnel involved with placing the catheter or monitoring the patient must be aware of such risk and use caution when changing bandages, administering fluids or medications, withdrawing blood, or manipulating three-way stopcocks on monitoring devices attached to the catheter. Infection will occur as a result of contaminated IV solutions, failure to maintain a strict protocol for skin preparation, poor insertion technique, failure to clean equipment between patients, or failure to routinely change the catheter bandage. Insertion sites should be monitored routinely for thrombosis, patient discomfort, catheter migration, and extravasation.

Phlebitis is a commonly encountered complication of indwelling vascular catheterization. Phlebitis can occur as a result of inflammation associated with movement of a stiff catheter in a vein or artery or from bacterial infection that can lead to sepsis. Aseptic technique should be used whenever possible to minimize infection. Catheters should also be routinely changed according to type (e.g., changing over-the-needle peripheral catheters every 72 hours and long over-the-needle central catheters every 120 hours into new anatomic site). Minimizing tape use and anchoring with suture to secure catheters aid in insertion site inspection and patient comfort. Polyurethane Seldinger-type central catheters (Arrow International) may stay in for the length of patient hospitalization but still need daily insertion site cleaning, inspection for signs of thrombosis or leakage, and daily bandage changes.

Bacterial contamination of catheter sites can result from caregiver handling, heparinized flush syringes, blood left inside an injection port, and even tops of medication bottles. Caregivers should practice proper hygiene protocols, including washing hands frequently, swabbing ports and medication bottles with antiseptics, and frequently changing bandages to any catheter in any anatomic location. Flush solution should also be changed every 48 hours to avoid microbial contamination.

Sterile technique and catheter care should be maintained for *any* type of fluid administration. However, nursing management of catheters used for parenteral nutrition warrants special focus because nutritional formulas are excellent mediums for bacterial colonization. Catheter care includes strict sterile technique during insertion, including proper skin preparation, placement of a sterile underwrap over insertion site, and strict aseptic technique in care of IV tubing and administration bags. The IV lines should not be disconnected; if diagnostic testing or frequent walking is necessary, the IV lines and administration bags should accompany the patient. Intravenous injections should follow sterilization of the port. If a multilumen catheter is placed, proper identification to each port is necessary, with one line dedicated to the total parenteral nutrition solution only (usually the proximal port).

CATHETER CARE

Arterial and cephalic catheter care should be performed every 24 hours. All supportive bandages should be removed, and the insertion site inspected for signs of phlebitis or thrombosis (i.e., redness, swelling, or ropelike vein). The catheter should be flushed with a small amount of heparinized saline (1 to 2 ml) using a pulsing movement while palpating tip of catheter. If any swelling or pain results from the flush, the catheter should be removed. If the patient is not on IV fluids, the catheter should be flushed every 4 hours (cephalic or jugular). Arterial catheters used for blood pressure monitoring should be flushed with heparinized saline every 2 hours or alternatively attached to a pressurized continuous-rate infusion which will maintain patency. When using the latter approach, it is important to maintain sufficient pressure in the cuff surrounding the fluid bag.

If the catheter is patent, the area should be cleaned with dilute povidone scrub or alcohol wipe and then dried. A small amount of povidone or antibiotic ointment can be placed over the insertion site before rebandaging the catheter. Recommended bandaging material is 2-inch tape (one piece to secure the catheter, and one piece to anchor a T-port, if used), cast padding in a single layer, followed by Kling gauze and vet wrap for the final layer. The date of placement of the catheter should be recorded, as well as the date of the rewrap. Catheters should be checked routinely every 2 hours for leakage or swelling. Swelling distal to the catheter usually indicates a tight bandage. Swelling proximal to the catheter could indicate extravasation of the administering fluid or medication.

Jugular catheter care also requires daily inspection as indicated previously. The insertion site should be cleaned with povidone solution and/or alcohol. Since the jugular catheter is significantly longer in length than the cephalic catheter, signs of extravasation may not be as apparent. The midsternal region should be examined for edema related to jugular venous catheter placement, and the proximal aspect of the medial hind limb should be examined for edema related to lateral or medial saphenous venous catheter placement. Bandaging material needed includes a 4×4 gauze pad with antibiotic ointment, followed by a single layer of casting padding, followed by Kling gauze and vet wrap. No tape is necessary to anchor a jugular catheter if it has been sutured in place. Note that neck bandages should have the “two-finger rule” (i.e., the bandage should be loose enough to slide two fingers under for patient comfort). If the jugular catheter is made of polyurethane material (i.e., Arrow International), it does not need to be changed out within a 90-day period. Other catheter types made from polypropylene material (MILA, Intracath) can be changed on the fifth day.

CHAPTER 8

Pacing in the Critical Care Setting

ANNA R.M. GELZER, *Ithaca, New York*
 MARC S. KRAUS, *Ithaca, New York*

Temporary cardiac pacing is a potentially lifesaving procedure for patients with severe bradyarrhythmias or those that are at a high risk of asystole in the emergency setting. Temporary cardiac pacing depends on rate support from an external pulse generator via electrodes that can be placed in a timely fashion and removed easily after a short period of pacing. Most situations requiring temporary pacing in veterinary medicine necessitate permanent pacing therapy, which will need to be initiated before removal of the temporary system (see Chapter 160).

This chapter focuses on two commonly used techniques in veterinary medicine: transcutaneous external pacing (DiFrancesco et al., 2003) and transvenous external pacing, procedures for which there are a number of clinical indications (Box 8-1). Transesophageal pacing may be used for atrial pacing, but ventricular capture is inconsistent. Because it has limited applicability to the veterinary critical care setting, it will not be discussed further.

Once the decision is made to support the heart rate by external pacing, pharmacologic interventions aimed at

Box 8-1

Indications for Temporary Pacing in the Critical Care Setting

- Asystole during cardiopulmonary arrest
- High grade second- or third-degree atrioventricular (AV) block with slow ventricular escape rhythm and secondary hemodynamic compromise or syncope
- Symptomatic sick sinus syndrome: frequent episodes of sinus arrest resulting in syncope
- Sinus bradycardia or second-degree AV block with hypotension not responsive to atropine or isoproterenol
- Ventricular tachyarrhythmias secondary to bradycardia
- Overdrive suppression of tachyarrhythmias
- Causes of transient medically refractory sinus bradycardia or AV block resulting in hemodynamic instability (i.e., drug toxicities):
 - Calcium channel blockers
 - β -Blocker
 - Digoxin

rate support (anticholinergics, sympathomimetics) should be discontinued. These drugs tend to be proarrhythmic and can sensitize the myocardium to stimulation from catheter manipulations, causing ventricular arrhythmias.

EXTERNAL TRANSCUTANEOUS TEMPORARY PACING

External transcutaneous pacing (TCP) generators come as stand-alone units or incorporated into a defibrillator. Both Zoll Medical Corp., Chelmsford, MA (M SERIES models) and Medtronic Inc., Minneapolis, MN (Lifepak models) feature user-friendly pacemaker/defibrillator units. Pacing can be achieved rapidly with very limited training and without a need to move a patient to fluoroscopy. However, TCP creates significant skin and muscle pain, necessitating general anesthesia for the duration of temporary pacing.

Materials and Technique Required for Transcutaneous Pacing

The materials required to provide TCP include airway and anesthetic equipment and the external pacing unit with two sets of electrodes. Electrocardiograph (ECG) electrodes are used for rhythm monitoring, and larger pacing electrode pads for cardiac stimulation. (Lifepak, Medtronic and Zoll Medical provide proprietary pads, but other companies also offer pacing pads that can be used with adaptors.) Pacing electrode pads come in pediatric and adult sizes. Pediatric pads should be used for animals less than 10 kg. If the animal is conscious but hemodynamically unstable because of a bradyarrhythmia, the TCP should be planned by first establishing intravenous access and ensuring that airway management can be provided once the patient is anesthetized. The animal's chest needs to be clipped over at least as large an area as the pacing pads will cover. The pads are placed over the right and left precordia. The caudal edge of the pad should be

positioned where the apex beat is felt strongest under the operator's hand; this "sandwiches" the heart between the pads. The ECG lead cables of the pacing unit need to be attached for the pacing system to monitor the inherent heart rhythm properly, including sensing of native electrical activity. While most units will also record the ECG from the thoracic electrode patches, rhythm monitoring during external pacing is best done from standard limb leads to reduce the confusion of local twitch artifact. It is important to place the ECG electrodes as far away from the pacing pads as possible to obtain a clear ECG signal on the pacing unit monitor. Set the pacing rate at 60 to 90 beats/min. The target heart rate is selected to maintain cardiac output and improve the blood pressure. For hemodynamically compromising bradycardia without cardiac arrest, start the pacing output at 0 mA, and increase the output by 10 mA until capture is achieved. In the asystole cardiac arrest setting, start at the maximum current setting and decrease the output to a value above where capture is lost. To achieve external pacing capture, a relatively high current output is required in dogs. Less than 70 or 80 mA does not usually result in successful capture, and most cases appear to require equal to or higher than 90 mA. The ECG generated by TCP should only be interpreted on the pacing unit monitor. A built-in filter and blanking protection change the high-output pacing stimulus to a smaller spike, preventing distortion of the ECG waveform. In contrast, regular ECG systems may display a huge pacing spike with no clearly identifiable ECG. In addition, chest thumping produced by TCP contributes to the artifactual appearance of the recordings from a regular ECG machine. To assess capture, look at the ECG tracing on the monitor for pacer spikes that are followed by both a QRS complex and a distinct T-wave. Electrical capture is manifest as a wide QRS complex, with a prominent T wave with opposite polarity of the QRS complex (Fig. 8-1). Both electrical and mechanical capture must be achieved to ensure cardiac output. Mechanical capture is only evidenced by a concurrent pulse (Fig. 8-2). Arterial pressure can be monitored with a direct arterial line, a Doppler sphygmomanometer system, or an oxygen saturation monitor displaying a pulse waveform. In the emergency setting palpation of a femoral pulse may be used. Skeletal muscle contractions occur with pacemaker current output as low as 10 mA and are not an indicator of electrical or mechanical capture. These become more intense as the current output is increased.

TCP is likely the least invasive and quickest means to achieve rate support in the course of cardiopulmonary resuscitation (CPR). It is safe to touch the patient or the pacing patches and perform CPR while TCP is ongoing. Since the patient is already unconscious, considerations regarding anesthesia for TCP are not applicable at that instant. However, it should be remembered that, if successful pacing is instituted, patients that were unconscious at the outset may regain consciousness, in which case general anesthesia must be readily available.

If surgery for a permanent pacemaker therapy is required following institution of TCP, it may be necessary to paralyze the animal during part of the surgery. The muscle stimulation of TCP can create so much body motion that surgical exposure of the jugular vein for

Fig. 8-1 **A**, ECG tracing of transcutaneous pacer unit with non-capture; the trace shows intermittent electrical capture. Arrows indicate paced beats. However, the second and fourth pacing stimuli do not result in capture (no QRS following the spike). The current output is set too low (60 mA) and should be increased. **B**, ECG tracing of transcutaneous pacer unit with capture. The trace shows continuous electrical capture. Each pacing spike is followed by a QRS complex. The current output was increased to 90 mA.

permanent pacemaker placement is impaired. In our experience large-breed dogs do not exhibit excessive twitching, but small-breed dogs and cats demonstrate significant whole-body thumping. To reduce muscle contractions, neuromuscular blockade with atracurium (0.1 to 0.2 mg/kg intravenously [IV] for 20 minutes' duration) is

very effective but requires manual or mechanical ventilation because of paralysis of the diaphragm.

If a permanent pacemaker is placed during TCP, one should be aware that the pacing stimulus is sensed as a far-field signal by the permanent pacemaker (if it is programmed VVI or demand-mode) even at currents as low as 1 mA. This means that the permanent pacemaker is inhibited to pace, even after the output of the transcutaneous pacer is reduced to loose capture. Blood pressure monitoring will reveal loss of pacing instantly. To avoid this, the heart rate of the transcutaneous pacer should be set lower than the permanent pacemaker so as to not inhibit pacing.

TRANSVENOUS TEMPORARY PACING

Transvenous pacing (TVP) is effective, comfortable once in place for the awake patient, and fairly stable if correctly positioned. Therefore it is the treatment of choice for prolonged temporary pacing. Several companies provide external-demand pacing units. Medtronic (model 5348) and Ocor Inc. (model Pace 101H) both feature user-friendly, stand-alone, and economical external pacers. Several types of catheters can be used for TVP. We use regular bipolar pacing catheters (No. 4 or 5 Fr) that can be connected directly to the external pacing generator. Alternatively, easy-to-advance balloon-tipped pacing leads are available (Balloon Flotation Bipolar Pacing Catheter, Arrow International Inc.).

Sedation for Placement of Transvenous Pacing Catheter

Transvenous pacing is most commonly used to bridge the time until permanent pacemaker implantation can be

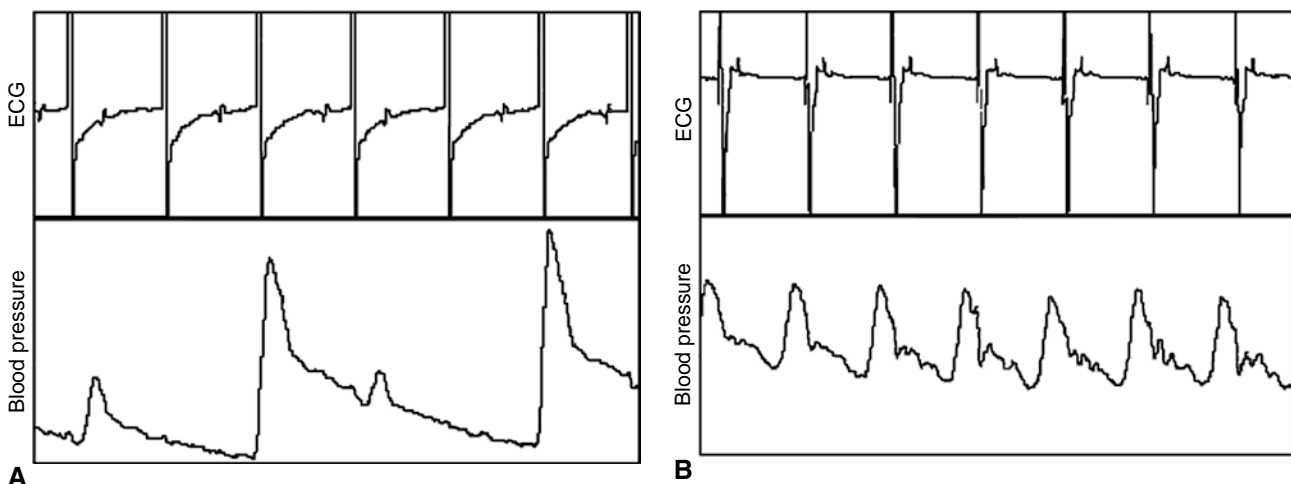

Fig. 8-2 **A**, Transthoracic pacing at 60 mA with no capture. Note that the surface ECG recorded with a regular physiorecorder shows large pacing spikes, obscuring the inherent ECG of the dog. Interpretation of the ECG alone would lead one to believe that there is adequate pacing. However, the blood pressure tracing reveals a discrepancy of heart rate between the ECG trace and the pressure trace because of lack of electrical and mechanical capture. The blood pressure trace shows the rate of the ventricular escape rhythm, displaying an irregular slow pulse. **B**, Transthoracic pacing at 90 mA with capture. Note that the surface ECG looks very similar to the example in panel A. The small positive deflection after the large pacing spike represents the QRS complex of electrical capture. However, only the concurrent blood pressure tracing confirms definitively that both electrical and mechanical capture is achieved.

performed. Since general anesthesia usually exacerbates bradyarrhythmias, the temporary pacing should be instituted before induction of general anesthesia. Light-to-heavy sedation and local anesthesia are usually required to insert the introducer sheath percutaneously. A combination of a sedative with a pain-relieving drug and an immobilizing agent is very effective. We like to use midazolam (0.3 to 0.5 mg/kg IV) with fentanyl (3 mcg/kg IV) and ketamine (1 to 2 mg/kg IV). If the animal needs to be even quieter, propofol (1 mg/kg IV) can be added. At the site of catheter insertion a local lidocaine block (2%, 0.5 ml SQ) should be infused to reduce pain. This protocol provides 10 to 20 minutes of sedation. The introducer sheath (No. 5 Fr, 6Fr, or 7 Fr Critical Care Arrow-Flex Polyurethane Sheath with Integral Hemostasis Valve/Side Port, Arrow International) is placed percutaneously using the modified Seldinger technique.

Placement of Transvenous Pacing Catheter

The proper choice of the insertion site is essential for success. If the temporary pacing lead is placed only to bridge a short time frame until permanent pacemaker surgery can be performed, we prefer to gain access via the femoral vein for TVP. This allows for a clean approach later to at least one or possibly both external jugular veins for the permanent pacing lead. However, if temporary pacing needs to last for several hours in the intensive care unit, the groin is not an optimal site for access. In an awake or only mildly sedated animal movement of the rear limb may displace the introducer sheath enough to pull out the pacing lead or result in local hemorrhage. If longer-term pacing is anticipated, a technically easier approach is cannulation of the external jugular vein. The right jugular vein is the shortest and most direct route, providing the most stable lead position. The introducer sheath can be secured safely to the skin and is subject to little movement if the neck is properly wrapped. The lateral saphenous vein may also be used for percutaneous access; however, we found that this approach can be impeded by the long distance and indirect route (i.e. navigating the catheter past the stifle joint is difficult because of the bend).

Except for sick sinus syndrome, in which right atrial pacing will suffice, most conditions requiring emergency pacing involve advanced atrioventricular (AV) block or

asystole, requiring ventricular pacing. Blind advancement of temporary pacing leads from the introducer sheath to the right ventricular apex is challenging. Monitoring the ECG for signs of capture of the pacing spike may be helpful, but frequently blind advancement results in catheter malposition. The catheter could enter the internal thoracic vein, the azygos vein, or the caudal vena cava or potentially curl up in the right ventricle. As a consequence of curling, pacing capture is poor or intermittent as a result of improper contact of the lead tip with the endomyocardial surface. Some balloon-tipped pacing catheters feature a lumen for pressure monitoring, which is helpful for blind placement. However, in our experience by far the fastest method is to use fluoroscopic guidance.

Optimally a pacing catheter is placed with fluoroscopic guidance. For ease of handling, we only connect to the external pacer once the lead is positioned properly in the right ventricular apex. However, if the lead has to be advanced blindly, it must be connected to the external pacer during the placement to use the continuous ECG for guidance. A small pacing spike can be visualized once the wire tip is near the heart, and capture of the atrial myocardium (P wave) may occur while the catheter is advanced toward the tricuspid valve. The pacing spike will be followed by a wide QRS complex once ventricular capture is established (Fig. 8-3).

In a true emergency situation such as during CPR, pacing has to be achieved without fluoroscopy. Since blind transvenous placement is almost impossible during chest compression, it may become inevitable to proceed to open-chest resuscitation to provide external rate support. In such instances the tip of the pacing lead can be held directly on the epicardial surface of the heart to achieve capture until the patient is stabilized, and fluoroscopic imaging can be used to place a lead transvenously.

EXTERNAL PACER PROGRAMMING

The external pacer should be set on demand-pacing, or VVI, mode. This means that it will pace the ventricle when needed but also sense the patient's intrinsic ventricular activity, which inhibits the pacer. This avoids stimulation during the vulnerable period (T wave) of the intrinsic beats to prevent induction of ventricular arrhythmias. The heart rate should be set to the minimum rate to achieve an adequate blood pressure. It is not advised to pace much faster

Fig. 8-3 Transvenous pacing. Surface ECG of a dog with third-degree atrioventricular block. The patient is being instrumented with a transvenous pacing catheter. After a long episode of asystole, a bipolar pacing spike is visualized, followed by a wide QRS complex, indicating successful ventricular capture.

than 80 to 90 beats/min unless absolutely necessary. In the case of sudden loss of capture, long episodes of sinus arrest may ensue as a result of overdrive suppression of the escape focus (the length of the pause is positively correlated to the preceding pacing rate). Typically ventricular capture by endocardial pacing can be achieved using between 1 to 5 V. Many temporary pacemakers do not indicate voltage but instead milliamperes of current output. If pacing resistance is low, capture is often obtained between 2 and 5 mA. The current threshold to achieve capture should be determined for each patient individually by gradually decreasing the voltage until loss of capture occurs. Twice threshold provides an adequate margin of safety. If the paced heart rate is less than the set rate, possible causes include: (1) poor lead position, (2) insufficient pacing voltage/current, (3) competing native rhythm (sinus capture, premature beats), and (4) T-wave sensing. T-wave sensing can be unmasked by briefly moving the selector switch to the full VOO (asynchronous) mode. If the paced rate is now correct, T-wave sensing is likely.

MONITORING OF PROLONGED TEMPORARY TRANSVENOUS PACING

Temporary TVP can be maintained for several days in an awake animal. Medically refractory drug toxicities such as overdose with a calcium channel blocker is an indication for longer-term temporary pacing. Aseptic technique during placement of the introducer sheath and pacing lead is imperative, and antibiotic coverage is recommended to prevent infection. The part of the lead extruding from

the introducer sheath should be aseptically covered inside the neck wrap. Since the temporary pacing leads have a smooth profile with no fixation mechanism, spontaneous displacement is likely. We suture a clip right outside the introducer sheath, which fits tight around the catheter and seems to fix it in place fairly well. The external pacing unit needs to be attached securely to the patient to avoid accidental traction on the pacing lead, and the generator batteries should be checked regularly. If ventricular capture becomes intermittent or requires greater than 5 V, lead displacement may have occurred, and a chest x-ray is indicated.

CHAPTER 9

Fluid Therapy

STEPHEN P. DIBARTOLA, *Columbus, Ohio*

SHANE W. BATEMAN, *Columbus, Ohio*

Fluid therapy is supportive. The underlying disease process that caused the fluid, electrolyte, and acid-base disturbances must be diagnosed and treated appropriately. Normal homeostatic mechanisms allow considerable margin for error in fluid therapy, provided that the heart and kidneys are normal. This is fortunate because clinical estimation of dehydration may be quite inaccurate. Fluid therapy potentially consists of three phases: resuscitation, rehydration, and maintenance. Most patients in shock require rapid administration of a large volume of crystalloid or colloid to expand the intravascular space and correct perfusion deficits. Dehydrated patients require sustained administration of crystalloid fluids for 12 to 36 hours to replace fluid losses from interstitial and intracellular spaces. Normally hydrated patients unable to consume sufficient water require maintenance fluid therapy with crystalloid solutions. In formulating a fluid therapy plan, eight questions should be considered:

1. Is the patient suffering from a shock syndrome that requires immediate fluid administration?
2. Is the patient dehydrated?
3. Can the patient consume an adequate volume of water to sustain normal fluid balance?
4. What type of fluid should be given?
5. By what route should the fluid be given?
6. How rapidly should the fluid be given?
7. How much fluid should be given?
8. When should fluid therapy be discontinued?

IS THE PATIENT SUFFERING FROM A SHOCK SYNDROME THAT REQUIRES IMMEDIATE FLUID ADMINISTRATION?

Shock patients urgently require fluid therapy. The presence of altered mental status and cool extremities in association with tachycardia or severe bradycardia, mucous membrane pallor, prolonged or absent capillary refill time, reduced or absent peripheral pulses, and hypotension are among the most common physical examination findings in patients in shock. Such physical examination findings and a compatible clinical history are the basis for the decision to institute a resuscitation phase of fluid therapy. Hypovolemic and distributive shock states are most likely to respond to intravascular volume expansion. Obstructive forms of shock often respond favorably to moderate volume expansion. Fluid administration is contraindicated in patients with cardiogenic forms of shock.

Regardless of their underlying disease, severely dehydrated patients can be in shock and require a resuscitation

phase of fluid therapy before initiating the rehydration phase. However, not all patients in shock are dehydrated, and some may not require a rehydration phase of therapy. The rapidity and volume of loss from both the intravascular and extravascular fluid compartments in conjunction with the extent of any compensatory response will determine whether the patient is in shock or is dehydrated.

IS THE PATIENT DEHYDRATED?

The need for a rehydration phase depends on the underlying condition of the patient and an assessment of the animal's state of hydration. The hydration status of the animal is estimated by careful evaluation of the history, physical examination findings, and the results of a few simple laboratory tests. In its most narrow sense dehydration refers to loss of pure water. However, the term *dehydration* usually is used to include hypotonic, isotonic, and hypertonic fluid losses. The type of dehydration is classified by the tonicity of the fluid remaining in the body (e.g., a hypotonic loss would result in hypertonic dehydration). Isotonic and hypotonic losses are most common in small animal practice. Severe volume depletion can result in nonosmotic stimulation of antidiuretic hormone (ADH) release, thus preventing effective excretion of consumed water and contributing to hypotonic dehydration.

Fluid Balance

Normally fluid input consists of water consumed in food, water that is drunk, and water produced metabolically in the body. Maintenance water and electrolyte needs parallel caloric expenditure; and normal daily losses of water and electrolytes include respiratory, fecal, and urinary losses. Respiratory loss of fluid can be important in dogs because panting has been adapted for thermoregulation in this species. Pyretic patients also can lose fluid by this route. Normally cutaneous losses are unimportant in dogs and cats because eccrine sweat glands are limited to the foot pads and do not play an important role in thermoregulation in these species.

In disease states decreased fluid intake results from anorexia, and increased fluid loss may occur by urinary (e.g., polyuria) and gastrointestinal (e.g., vomiting, diarrhea) routes. Less common routes of loss include skin (e.g., extensive burns), respiratory tract, and salivary secretions. Third-space loss of fluid occurs when effective circulating volume is decreased but the fluid lost remains in the body. Examples include intestinal obstruction,

peritonitis, pancreatitis, and effusions or hemorrhage into body cavities. Decreased fluid intake and increased loss often coexist (e.g., anorexia, vomiting, and polyuria in a uremic animal).

History

The history may suggest the affected fluid compartment or compartments, as well as the patient's electrolyte and acid-base derangements. The time period over which fluid losses have occurred and an estimate of their magnitude should be determined. Information about food and water consumption, gastrointestinal losses (e.g., vomiting, diarrhea), urinary losses (i.e., polyuria), and traumatic losses (e.g., blood loss, extensive burns) should be obtained. Excessive insensible water losses (e.g., increased panting, pyrexia) and third-space losses may be determined from the history and physical examination. The clinician's knowledge of the suspected disease can aid in predicting the composition of the fluid lost (e.g., vomiting caused by pyloric obstruction leads to loss of hydrogen, chloride, potassium, and sodium ions and development of metabolic alkalosis; small-bowel diarrhea typically leads to loss of bicarbonate, chloride, sodium, and potassium ions and development of metabolic acidosis).

Physical Examination

Physical findings associated with fluid losses of 5% to 15% of body weight vary from no clinically detectable changes (5%) to signs of hypovolemic shock and impending death (15%). The hydration deficit is estimated by evaluating skin turgor, moistness of the mucous membranes, position of the eyes in their orbits, heart rate, character of peripheral pulses, capillary refill time, and extent of peripheral venous distention (i.e., inspection of jugular veins). A decrease in the interstitial compartment volume leads to decreased skin turgor and dryness of the mucous membranes. A decrease in plasma volume leads to tachycardia, alterations in peripheral pulses, and collapse of peripheral veins. When these cardiovascular signs are present, the patient is in shock and should be resuscitated promptly before correction of the hydration deficit. Typically such signs of hypovolemic shock appear with fluid loss that amounts to 10% to 12% of the patient's body weight. The fluid deficit in a given patient is difficult to determine with accuracy because of the subjectivity of skin turgor evaluation and the possibility of undetected ongoing (contemporary) losses. When evaluated by skin turgor, obese animals may appear well hydrated as a result of excessive subcutaneous fat despite being dehydrated. Conversely, emaciated and older animals may appear more dehydrated than they actually are because of lack of subcutaneous fat and elastin. Thus a crude clinical estimate of hydration status and the patient's response to fluid administration become important tools in evaluating the extent of dehydration and planning fluid therapy. The urinary bladder should be small in a dehydrated animal with normal renal function. In the absence of urinary obstruction, a large bladder in a severely dehydrated patient indicates failure of the normal renal concentrating mechanism.

Body weight recorded on a serial basis traditionally has been considered a good indicator of hydration status, especially when fluid loss has been acute and previous body weight has been recorded (i.e., 1-kg loss of body weight equals a 1-L fluid deficit). However, in one study clinician estimates of hydration in dogs and cats admitted to a veterinary teaching hospital intensive care unit did not reliably predict changes in weight after 24 to 48 hours of fluid therapy. In chronically ill animals loss of weight also includes loss of muscle mass. Anorexic animals have been estimated to lose 0.1 to 0.3 kg of body weight per day per 1000 kcal energy requirement. Losses in excess of this amount indicate fluid loss. Another factor that must be considered in evaluating body weight is the possibility of third-space loss. Fluid lost into a third space does not decrease body weight.

Laboratory Findings

Packed cell volume (PCV), total plasma protein concentration (TPP), and urine specific gravity (USG) are simple laboratory tests that aid in the evaluation of hydration. These results should be obtained before initiating fluid therapy. PCV and TPP should be evaluated together to minimize errors in interpretation. PCV and TPP increase with all types of fluid losses excluding hemorrhage; whereas serum sodium concentration increases, decreases, or remains unchanged, depending on the type of loss (e.g., hypotonic, hypertonic, isotonic) and the presence or absence of nonosmotic stimulation of ADH release. The USG before fluid therapy is helpful in the preliminary evaluation of renal function. It should be high (>1.045) in a dehydrated dog or cat if renal function is normal. This may not be true if other disorders affecting renal concentrating ability such as medullary washout of solute are present. Furthermore, previous administration of corticosteroids or furosemide can decrease urinary concentrating ability.

CAN THE PATIENT CONSUME AN ADEQUATE VOLUME OF WATER TO SUSTAIN NORMAL FLUID BALANCE?

Volume-resuscitated and rehydrated patients may not have recovered sufficiently to eat and drink normally. Such patients require ongoing fluid therapy. Maintenance fluid requirements have been determined from studies of normal animals, and the needs of partially or completely anorexic dogs and cats are not well understood. Also, absorption and metabolism of nutrients produce solutes that must be excreted in urine. Sensible fluid losses and urine production are decreased during fasting in normal animals because less solute requires excretion. Typically fluids are administered to veterinary patients in volumes predicated on the needs of animals that are not anorexic. Careful observation of urine production in such patients is warranted. If the patient has normal renal concentrating ability but is producing large volumes of dilute urine, excessive fluid administration likely is a contributing factor. Reduction of fluid administration and careful observation are warranted in such patients.

WHAT TYPE OF FLUID SHOULD BE GIVEN?

The composition of a *balanced* fluid (e.g., lactated Ringer's solution, Normosol-R, Plasma-Lyte 148) resembles that of extracellular fluid (ECF); whereas that of an *unbalanced* solution (e.g., normal saline) does not. Fluid preparations may be further classified as *crystalloids* or *colloids*. Crystalloids (e.g., 5% dextrose, 0.9% saline, lactated Ringer's solution) are solutions containing electrolyte and nonelectrolyte solutes capable of entering all body fluid compartments. Colloids are large-molecular weight substances that normally are restricted to the plasma compartment and include plasma, dextrans, hydroxyethyl starch (hetastarch), and hemoglobin-based oxygen-carrying fluids.

Crystalloid solutions expand the plasma compartment with equal effectiveness, but 2.5 to 3 times as much crystalloid solution must be given (compared with a colloid solution) because the crystalloid is distributed to other sites (e.g., interstitial compartment, intracellular compartment). Pulmonary capillaries normally are more permeable to protein, resulting in a higher interstitial concentration of protein and more resistance to leakage of fluid from capillaries. Peripheral edema is more likely to occur after crystalloid administration than pulmonary edema because muscle and subcutaneous capillaries are less permeable to protein.

Crystalloid solutions also can be classified as *replacement* or *maintenance* solutions. The composition of replacement solutions (e.g., lactated Ringer's, Normosol-R, Plasma-Lyte 148) resembles that of ECF. Maintenance solutions (e.g., Normosol-M, Plasma-Lyte 56) contain less sodium (40 to 60 mEq/L) and more potassium (15 to 30 mEq/L) than replacement fluids. Administering 5% dextrose (another commonly used crystalloid) is equivalent to giving water because the glucose is oxidized to CO₂ and water. In fact, the main reason for giving 5% dextrose is to correct a pure-water deficit. Except in very small animals, 5% dextrose cannot be relied on to maintain daily caloric needs because it provides only 200 kcal/L. Most animals that require fluid therapy can be managed with a limited number of crystalloid and additive solutions. The most useful crystalloid solutions for routine use are a balanced replacement solution (e.g., lactated Ringer's solution, Normosol-R, Plasma-Lyte 148), 0.9% saline, and 5% dextrose in water. Supplementation of crystalloid solutions with KCl may be necessary when body fluid losses have included large amounts of potassium. An empiric scale can be used to estimate the amount of potassium to add to parenterally administered fluids (Table 9-1). Other additive solutions include 50% dextrose, calcium chloride, calcium gluconate, potassium phosphate, 8.4% sodium bicarbonate, and water-soluble B vitamins.

The choice of fluid to administer depends on the nature of the disease process and the composition of the fluid lost. The patient's acid-base and electrolyte disturbances should be considered when choosing a fluid, and losses should be replaced with a fluid similar in volume and electrolyte composition to the fluid that has been lost. If clinical assessment of the patient suggests a fluid-responsive type of shock, the resuscitation phase of fluid therapy should be instituted. If the patient has abnormally low oncotic pressure or a disease that would benefit from low-volume resuscitation, synthetic colloids should be con-

Table 9-1

Sliding Scale for Potassium Supplementation

Serum Potassium Concentration (mEq/L)	mEq KCl to Add to 250 ml Fluid	Maximal Fluid Infusion Rate (ml/kg/hr)*
<2.0	20	6
2.1-2.5	15	8
2.6-3.0	10	12
3.1-3.5	7	16

* So as not to exceed 0.5 mEq/kg/hr.

sidered for resuscitation. If neither of these considerations applies, resuscitation with a balanced crystalloid solution is sufficient. If clinical signs of hypovolemia are not present, the hydration deficit and maintenance needs may be combined and administered during the next 24 hours.

Persistent vomiting caused by pyloric obstruction results in losses of hydrochloric acid, potassium, sodium, and water, potentially producing hypokalemia, hypochloremia, and metabolic alkalosis. The initial fluid of choice in this setting is 0.9% NaCl with 20 to 30 mEq of KCl per liter. Except in the case of vomiting of stomach contents, lactated Ringer's is a good first choice for fluid therapy while awaiting laboratory results. Normal saline (0.9% NaCl) is less ideal because it is not a balanced solution. It has a high chloride concentration relative to ECF (154 mEq/L versus 110 mEq/L in dogs and 120 mEq/L in cats) and is mildly acidifying because the chloride displaces bicarbonate in ECF.

Anions such as acetate, gluconate, and lactate are added to crystalloid solutions as a source of base because their oxidative metabolism in the body yields bicarbonate. For example, in the case of lactate:

Most lactate is produced in muscle and gut and metabolized to either glucose (via cytosolic gluconeogenesis) or CO₂ and water (via mitochondrial oxidation) in the liver. Normally gluconeogenesis predominates. Acetate is metabolized primarily in muscle. The alkalinizing effect of these anions is delayed because of the requirement for metabolism. Most patients treated with lactate-containing replacement solutions respond well, probably as a result of ECF volume expansion and improved tissue perfusion.

Whether converted to glucose or oxidized to CO₂ and water, lactate metabolism consumes hydrogen ions and has an alkalinizing effect:

Concern sometimes is expressed that the lactate in lactated Ringer's solution may be harmful to patients with poor tissue perfusion and severe metabolic acidosis (pH <7.1 to 7.2).

Administration of lactate as a salt cannot contribute directly to metabolic acidosis. Rather, the ability of the liver to metabolize lactate and the potentially detrimental effect of lactate on myocardial contractility are debated. During severe hypoxia increased lactate production in gut and muscle and decreased hepatic extraction of lactate may lead to progressive lactic acidosis. In moderate metabolic acidosis administration of lactated Ringer's solution probably is beneficial because any tendency toward lactate accumulation likely is offset by improved hepatic perfusion and oxygen delivery as a result of ECF volume expansion. Some balanced crystalloid solutions (e.g., Plasma-Lyte 148, Normosol-R) contain approximately twice the amount of bicarbonate precursors when compared with lactated Ringer's solution. As a result, these solutions generally are thought to be more efficient than lactated Ringer's solution in treatment of metabolic acidosis, provided that metabolic conversion of the precursors to bicarbonate occurs quickly.

BY WHAT ROUTE SHOULD FLUIDS BE GIVEN?

The route of fluid therapy depends on the nature of the clinical disorder, its severity, and its duration. The *intravenous* route is preferred when the patient is very ill, when fluid loss is severe, or when fluid loss is acute. The intravenous route provides rapid dispersion of water and electrolytes and allows precise dosage. A large volume can be given rapidly, and hypertonic fluids can be given safely via a large vein. Vascular access is required, and close monitoring is necessary to avoid complications such as overhydration, thromboembolism, phlebitis, and infection. Veins available for vascular access include the jugular, cephalic, lateral saphenous, and femoral veins. There are advantages and disadvantages of each, but the jugular vein is useful because it allows delivery of large volumes, administration of hypertonic or potentially irritating solutions, measurement of central venous pressure (CVP), and repeated venous blood sampling. The cephalic vein also is commonly used, but fluid delivery can be hindered by flexion of the elbow, and extremely hypertonic or irritating solutions should not be used. Intravenous catheter function and the catheter-skin interface should be monitored routinely to detect complications. Catheters that remain clean and free of complications need not be replaced at a routine interval.

The *subcutaneous* route is convenient for maintenance fluid therapy in small dogs and cats. The subcutaneous space in dogs and cats can accommodate relatively large volumes of fluid, and potassium can be used in concentrations up to 30 mEq/L without irritation. Approximately 10 ml/kg or 50 to 200 ml may be administered per site. Volume overload is unlikely to occur when fluids are administered subcutaneously in patients with no underlying cardiac insufficiency. Furthermore, some owners can use subcutaneous administration to give fluids at home to animals with chronic disease problems. The subcutaneous route is not adequate for patients with acute and severe losses (e.g., shock) and is not recommended for

extremely dehydrated or hypothermic animals because peripheral vasoconstriction may reduce absorption and dispersion of the administered fluid in these settings. The volume that may be given is limited by skin elasticity, and this route is not useful in larger animals requiring large volumes of fluids. Irritating or hypertonic solutions should not be used subcutaneously; only isotonic fluids are recommended. Isotonic fluids containing bicarbonate precursors other than lactate also are not recommended for subcutaneous administration. Although not harmful, they may cause mild local discomfort. Subcutaneous administration of 5% dextrose in water should be avoided because equilibration of ECF with a pool of electrolyte-free solution may lead to temporary aggravation of electrolyte imbalance.

The *oral* route is most physiologic, and fluids with a wide variety of compositions may be given. Oral fluid therapy is useful for administering hypertonic fluids with high caloric density. Fluid can be administered rapidly with minimal adverse effects, and caloric needs can be met. However, this route cannot be used in the presence of gastrointestinal dysfunction (e.g., vomiting, diarrhea). The oral route also is inadequate in animals with acute or extensive fluid losses because the administered fluid and electrolytes are not dispersed rapidly enough. In anorexic animals without vomiting or diarrhea, fluid can be administered orally using a number of different techniques (e.g., nasogastric, esophagostomy, or gastrostomy tube). Other uncommonly used routes of fluid administration include the *intraperitoneal* and *intramedullary* routes.

HOW FAST MAY FLUIDS BE GIVEN?

The rate of fluid administration is dictated by the magnitude and rapidity of the fluid loss. The patient with fluid-responsive shock syndrome requires aggressive fluid administration. Fluid administration rates may vary, depending on the type of fluid that has been chosen. One approach is to calculate a "shock fluid dose" and administer it as rapidly as possible in divided aliquots until a stable and sustainable cardiovascular end point has been achieved. Clinical evaluation of the patient should occur after administration of each aliquot using a "titrate to effect" approach. The shock dosage of synthetic colloids is 20 ml/kg for dogs and 10 to 15 ml/kg for cats. The shock dosage of isotonic crystalloids is 80 to 90 ml/kg for dogs and 40 to 60 ml/kg for cats. Contemporary losses also must be considered when adjusting the rate of fluid administration. Severe ongoing losses (e.g., vomiting and diarrhea in a patient with acute gastroenteritis) may necessitate rapid administration to keep pace with contemporary fluid loss. When fluids are given rapidly, cardiovascular and renal function should be monitored.

It usually is not necessary or desirable to replace the hydration deficit rapidly in chronic disease states. Instead, the hydration deficit may be calculated, the daily maintenance requirement of fluid added to this amount, and the total volume administered over 24 hours. Ongoing or contemporary losses also must be taken into consideration when estimating the patient's fluid requirements for a 24-hour period.

Infusion pumps are available for clinical use and provide a highly accurate record of the volume infused. Widespread availability of affordable electronic fluid pumps has facilitated fluid therapy in veterinary practice. Although use of infusion pumps makes fluid administration safer and more accurate, the equipment must be used appropriately, maintained in good working order, and tested regularly for accuracy. Mistakes in fluid administration still can occur as a consequence of human error or equipment failure.

HOW MUCH FLUID SHOULD BE GIVEN?

The purpose of fluid therapy is to increase tissue perfusion, repair fluid deficits, supply daily fluid needs, and replace ongoing losses.

Components of Fluid Therapy

The volume requirements of patients with fluid-responsive shock syndromes can vary widely. The goal of reestablishing widespread effective tissue perfusion dictates the volume of fluid administered. In general, the cardiovascular parameters used to characterize the patient's shock syndrome should return to normal (or to the extent they are able to do so considering the limitations of the patient's underlying disease). For example, a severely dehydrated dog with tachycardia, pale mucous membranes, prolonged capillary refill time, and hypotension should receive a volume of fluid sufficient to return these cardiovascular parameters to normal; and these parameters should not deviate from normal when the rate of fluid administration is decreased and rehydration of the patient begun. In patients without ongoing loss of fluid from the intravascular compartment or other more complex cardiovascular derangements, response to fluid resuscitation should be rapid and complete.

The initial assessment of hydration determines the volume of fluid needed to correct the hydration deficit (*replacement requirement*). The hydration deficit is calculated as the percentage of dehydration (estimated by physical examination) times the patient's body weight in kilograms. The resultant value is the fluid deficit in liters. During the rehydration phase of therapy this volume is administered over 24 hours in conjunction with maintenance fluid requirements and replacement of ongoing or contemporary losses.

Coincident with or after replacement of the animal's hydration deficit, the *maintenance requirement* must be administered. The maintenance fluid requirement is the volume needed each day to keep the animal in balance (i.e., no net change in body water). The maintenance fluid requirement for dogs and cats can be determined from reference charts that use formulas based on energy expenditure to calculate accurate daily fluid requirements. Although estimates of 40 to 60 ml/kg/day frequently are used to calculate maintenance fluid requirements, such estimates are only accurate for some animals. Cats, very small dogs, and very large dogs are not well served by the use of such estimates; these patients may benefit from more accurate assessment of their fluid requirements. Approximately two thirds of the maintenance require-

ment represents sensible (i.e., easy to measure) losses of fluid (i.e., urine output), and one third represents insensible (i.e., difficult to measure) losses (i.e., primarily fecal and respiratory water loss). Thus daily maintenance for a 10-kg dog may be 600 ml, with 400 ml representing sensible loss and 200 ml representing insensible loss. Some clinicians multiply maintenance fluid requirements by some factor between 1 and 3 to estimate the patient's 24-hour fluid needs. Assuming 60 ml/kg/day for maintenance, the information in Table 9-2 can be used to quickly estimate the implied hydration deficit and actual rate of fluid administration using this approach.

In addition to the hydration deficit (replacement requirement) and maintenance requirement, *contemporary (ongoing) losses* must be considered. These are not always easily determined but can be very important. Ongoing losses (including those caused by vomiting, diarrhea, polyuria, large wounds, drains, peritoneal or pleural losses, panting, fever, and blood loss) should be estimated and carefully replaced along with the maintenance volume of fluid. Box 9-1 summarizes the components of fluid therapy and their calculation.

Table 9-2

Maintenance and Dehydration Fluid Volume Requirements

Maintenance (M) + Dehydration (%)	ml/kg/day	Factor × Maintenance
M	60	1.00
M + 1	70	1.17
M + 2	80	1.33
M + 3	90	1.50
M + 4	100	1.67
M + 5	110	1.83
M + 6	120	2.00
M + 7	130	2.17
M + 8	140	2.33
M + 9	150	2.50
M + 10	160	2.67
M + 11	170	2.83
M + 12	180	3.00

Box 9-1

Components of Fluid Therapy

Hydration Deficit (Replacement Requirement)

Body weight (kg) × % dehydration as a decimal = deficit in liters

Maintenance Requirement (40-60 ml/kg/day)

Sensible losses (urine output): 27-40 ml/kg/day
Insensible losses (fecal, cutaneous, respiratory): 13-20 ml/kg/day

Contemporary (Ongoing) Losses (e.g., Vomiting, Diarrhea, Polyuria)

Failure to Achieve Rehydration

Repeated assessment of the patient by observation of clinical signs and determinations of body weight, urine output, PCV, TPP, and USG is necessary to make appropriate adjustments in fluid therapy. Reasons for failure to achieve satisfactory rehydration include calculation errors, underestimation of the initial hydration deficit, contemporary losses larger than appreciated, excessively rapid infusion of fluid with diuresis and urinary loss of fluid and electrolytes, administered fluid not reaching the ECF (e.g., technical problems, third-space loss), sensible losses larger than appreciated (i.e., polyuria), and insensible losses larger than appreciated (e.g., panting, fever). Failure to achieve successful hydration is an indication to increase the volume of fluid administered if the heart and kidneys are functioning adequately. As a rule the daily fluid volume may be increased by an amount equivalent to 5% of body weight if the initial infusion fails to restore hydration. Finally, if the animal does not gain weight despite several days of fluid therapy, the possibility must be considered that the animal was not dehydrated at presentation (e.g., abnormal skin turgor related to old age or emaciation).

MONITORING FLUID THERAPY

The hydration deficit determined by history and physical examination is only an estimate, and fluid therapy must be tailored to physical (e.g., body weight) and laboratory (e.g., PCV, TPP) findings during the first few days of fluid therapy.

Physical and Laboratory Findings

Physical examination, including evaluation of skin turgor and thoracic auscultation, should be performed once or twice daily on animals receiving fluids. PCV, TPP, and body weight should be monitored. Serial body weight is an important variable to follow, and animals receiving fluids should be weighed daily using the same scale. A gain or loss of 1 kg can be considered an excess or deficit of 1 L of fluid because lean body mass is not gained or lost quickly. A dehydrated patient should gain weight as rehydration is achieved, and afterward weight should remain relatively constant. However, weight may increase without restoration of effective circulating volume in patients with severe third-space losses. Despite these principles, clinical estimates of dehydration did not reliably predict changes in body weight after 24 to 48 hours of fluid therapy in one study.

Urine Output

The animal's urine output should be observed carefully after fluid therapy has begun. Oliguria should be suspected in patients with acute renal failure, especially those with possible ethylene glycol ingestion. Urine output (normal, 1 to 2 ml/kg/hour) should be monitored when fluids are administered intravenously at a rapid rate and renal function is in question. As the patient becomes rehydrated, physiologic oliguria should resolve, and urine output should increase. If oliguria present at admission persists after the hydration deficit has been corrected, daily fluid

therapy should be divided into six 4-hour intervals if the status of renal function is uncertain. The calculated insensible volume plus a volume equal to the urine output of the previous 4 hours is administered during each 4-hour period (known as measuring "ins and outs"). The risk of overhydration is minimized, and fluid therapy keeps pace with urine output even if oliguria is present when this technique is used. If oliguria persists, increasing the daily fluid volume by an amount equal to 5% of body weight is justified on the assumption that the initial estimate of dehydration was inaccurate. If oliguria does not respond to mild volume expansion, administration of increased volumes of fluid may result in pulmonary edema.

Central Venous Pressure

Measurement of CVP (normal, 0 to 3 cm H₂O) with a jugular catheter positioned at the level of the right atrium allows the cardiovascular response to fluid administration to be monitored. CVP increases from below normal into the normal range when fluids are administered to a dehydrated animal. A progressive increase in CVP above normal during fluid therapy is an indication to decrease the rate of fluid administration or to stop fluid therapy temporarily. A sudden and sustained increase in CVP may indicate failure of the cardiovascular system to handle the fluid load effectively and could result in pulmonary edema caused by left-sided heart failure. In addition to the volume of fluid administered, other factors that may affect CVP include heart rate, vascular capacity, and cardiac contractility. A reduction in any of these three parameters could cause an increase in CVP.

Complications of Fluid Therapy

Signs of overhydration occur when fluid is administered too rapidly. These may include serous nasal discharge, chemosis, restlessness, shivering, tachycardia, cough, tachypnea, dyspnea, pulmonary crackles and edema, ascites, polyuria, exophthalmos, diarrhea, and vomiting. Expected laboratory abnormalities include a reduction in PCV and TPP and an increase in body weight.

When the intravenous route is chosen for fluid therapy, the clinician has made a commitment to careful, aseptic catheter placement and proper maintenance. The animal should be checked daily for cleanliness of the catheter site, local pain or swelling, fever, or cardiac murmurs. If any of these signs are observed, the catheter should be removed, its tip cultured, the patient started on appropriate antibiotic therapy, and a new catheter placed in another vein. Complications related to catheter placement include bacterial endocarditis, thrombophlebitis, and thromboembolism. When not in use, the catheter should be irrigated with a small volume (<1 ml) of a solution containing 1 to 5 U of heparin per milliliter of 0.9% NaCl ("heparinized saline").

WHEN SHOULD FLUID THERAPY BE DISCONTINUED?

Ideally fluid therapy is discontinued when hydration is restored and the animal can maintain fluid balance on its own by eating and drinking. As the animal recovers,

fluid therapy usually is tapered by decreasing the volume of fluid administered by 25% to 50% per day. If an animal remains anorexic for more than 3 to 5 days, enteral or parenteral nutritional therapy must be considered.

CHAPTER 10

Acid-Base Disorders

HELIO AUTRAN DE MORAIS, *Madison, Wisconsin*

STEPHEN P. DIBARTOLA, *Columbus, Ohio*

Acid-base disorders are often encountered in critical care and outpatient settings in association with several conditions. A clear understanding of metabolic-respiratory interactions and a systematic approach aimed at identifying the separate components of acid-base disorders not only serve as a diagnostic tool, but also help in formulating therapeutic interventions. For example, abnormal acid-base balance may be harmful in part because of the patient's response to the abnormality, as when a spontaneously breathing patient with metabolic acidosis attempts to compensate by increasing minute ventilation. Such a response may lead to respiratory muscle fatigue with respiratory failure or diversion of blood flow from vital organs to the respiratory muscles, eventually resulting in organ injury. Thus it is important to understand both the causes of acid-base disorders and the limitations of various treatment strategies.

Blood pH and bicarbonate concentration can change secondary to changes in carbon dioxide tension (P_{CO_2}), strong ion difference (SID), or total plasma concentration of nonvolatile weak buffers (A_{tot}). Respiratory acid-base disorders occur whenever there is a primary change in P_{CO_2} , whereas metabolic acid-base disorders occur whenever SID or A_{tot} is changing primarily. Changes in SID or A_{tot} can be identified clinically by alterations in HCO_3^- concentration or base excess (BE). The SID is the difference between all strong cations and all strong anions. Strong ions are fully dissociated at physiologic pH and therefore exert no buffering effect. However, strong ions do exert an electrical effect because the sum of completely

dissociated cations does not equal the sum of completely dissociated anions. Because strong ions do not participate in chemical reactions in plasma at physiologic pH, they act as a collective positive unit of charge, the SID. The quantitatively most important strong ions in plasma are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , lactate, β -hydroxybutyrate, acetate, and SO_4^{2-} . The influence of strong ions on pH and HCO_3^- concentration can always be summarized in terms of the SID. Changes in SID of a magnitude capable of altering acid-base balance usually occur as a result of increasing concentrations of Na^+ , Cl^- , SO_4^{2-} , or organic anions or decreasing concentrations of Na^+ or Cl^- . An increase in SID (by decreasing Cl^- or increasing Na^+) causes a strong ion (metabolic) alkalosis, whereas a decrease in SID (by decreasing Na^+ or increasing Cl^- , SO_4^{2-} , or organic anions) causes a strong ion (metabolic) acidosis. The main non-volatile plasma buffers that constitute A_{tot} act as weak acids at physiologic pH (e.g., phosphate, imidazole [histidine] groups on plasma proteins). An increase in the total concentration of phosphate leads to A_{tot} (metabolic) acidosis, whereas a decrease in albumin concentration causes A_{tot} (metabolic) alkalosis.

STEPWISE APPROACH

A routine methodic approach to interpretation of blood gas data facilitates the clinician's assessment of the patient. The first step is a careful history to search for clues that may lead the clinician to suspect the presence of acid-base disorders, followed by a complete physical examination.

Obtain Simultaneous Blood Gas Measurement and Chemistry Profile

Blood pH can vary as a result of changes in P_{CO_2} , SID, and weak and strong acid concentration. Some strong ions (Na^+ , Cl^- , and K^+) and the most important weak acids (albumin and inorganic phosphates) are part of the chemistry profile and help understand why pH is changing.

Identify the Primary Disturbance

The clinician should first consider the patient's blood pH. The primary disturbance (respiratory or metabolic) can be identified by determining if P_{CO_2} or HCO_3^- is changing in the same direction that pH changed. There are four classic primary acid-base disorders: respiratory alkalosis, respiratory acidosis, metabolic alkalosis, and metabolic acidosis. Metabolic acid-base disorders can be divided further based on changes in SID or A_{tot}^* .

Calculate the Expected Compensation

Any alteration in acid-base equilibrium sets into motion a compensatory response by either the lungs or the kidneys. The compensatory response attempts to return the ratio between P_{CO_2} and HCO_3^- to normal and thereby minimize the pH change. A primary increase or decrease in one component is associated with a predictable compensatory change in the same direction in the other component (Table 10-1). Adaptive changes in plasma

Table 10-1

Compensatory Response in Simple Acid-Base Disturbances in Dogs and Cats*

CLINICAL GUIDE FOR COMPENSATION		
Disturbance	Dogs	Cats
Metabolic acidosis	\downarrow in $P_{\text{CO}_2} = 0.7 \times$ \downarrow in HCO_3^-	P_{CO_2} does not change
Metabolic alkalosis	\uparrow in $P_{\text{CO}_2} = 0.7 \times$ \uparrow in HCO_3^-	\uparrow in $P_{\text{CO}_2} = 0.7 \times$ \uparrow in HCO_3^-
Respiratory Acidosis		
Acute	\uparrow in $\text{HCO}_3^- = 0.15 \times$ \uparrow in P_{CO_2}	\uparrow in $\text{HCO}_3^- = 0.15 \times$ \uparrow in P_{CO_2}
Chronic	\uparrow in $\text{HCO}_3^- = 0.35 \times$ \uparrow in P_{CO_2}	Unknown
Long-standing (> 30 days)	\uparrow in $\text{HCO}_3^- = 0.55 \times$ \uparrow in P_{CO_2}	Unknown
Respiratory Alkalosis		
Acute	\downarrow in $\text{HCO}_3^- = 0.25 \times$ \downarrow in P_{CO_2}	\downarrow in $\text{HCO}_3^- = 0.25 \times$ \downarrow in P_{CO_2}
Chronic	\downarrow in $\text{HCO}_3^- = 0.55 \times$ \downarrow in P_{CO_2}	Similar to dogs

*Modified from de Morais HSA, DiBartola SP: Ventilatory and metabolic compensation in dogs with acid-base disorders, *J Vet Emerg Crit Care* 1(2):39, 1991; and de Morais HSA, Leisewitz A: Mixed acid-base disorders. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders*, ed 3, Philadelphia, 2006, Elsevier, p 296.

HCO_3^- in respiratory disorders occur in two phases: acute and chronic. In respiratory acidosis the first phase represents titration of nonbicarbonate buffers, whereas in respiratory alkalosis the first phase represents release of H^+ from nonbicarbonate buffers within cells. This response is completed within 15 minutes. The second phase reflects renal adaptation and consists of increased net acid excretion and increased HCO_3^- resorption (decreased Cl^- resorption) in respiratory acidosis and a decrease in net acid excretion in respiratory alkalosis. Adaptive respiratory response to metabolic disorders begins immediately and is complete within hours. Some guidelines for use of compensatory rules from Table 10-1 are presented in Box 10-1.

The definition of a simple acid-base disturbance includes both the primary process causing changes in P_{CO_2} or HCO_3^- and the compensatory mechanisms affecting these measurements. Lack of appropriate compensation is evidence of a mixed acid-base disorder. Compensation is said to be inappropriate if a patient's P_{CO_2} differs from expected P_{CO_2} by more than 2 mm Hg in a primary metabolic process or if a patient's HCO_3^- differs from the expected HCO_3^- by more than 2 mEq/L in a respiratory acid-base disorder.

Calculate Gaps and Gradients

Calculating the various gaps and gradients can be useful in evaluation of acid-base disorders (Box 10-2).

Strong Ion Gap and Anion Gap

Increase in the *anion gap* (AG) and *strong ion gap* (SIG) are associated with increase in concentration of unmeasured anions, both strong (e.g., lactate, acetoacetate,

Box 10-1

Guidelines for Adequate Use of Compensatory Rules From Table 10-1

Time

Sufficient time must elapse for compensation to reach a steady state:

Acute respiratory disorders:	15 minutes
Chronic respiratory disorders:	7 days
Long-standing respiratory acidosis:	30 days
Metabolic disorders:	24 hours

pH

- Compensation does not return the pH to normal*
- Overcompensation does not occur

Values in the expected compensatory range:

- Do not prove that there is only one disturbance
- Provide support for a simple acid-base disturbance, if consistent with the remaining clinical data

*Exceptions: Chronic respiratory alkalosis (>14 days), and potentially long-standing respiratory acidosis (>30 days).

Box 10-2

Gaps and Gradients in Acid-Base Disorders**Estimation of Unmeasured Anions During Metabolic Acidosis****Anion gap (AG)**

$$AG = (Na^+ + K^+) - (HCO_3^- + Cl^-)$$

Strong ion gap (SIG)

$$SIG = [albumin] \times 4.9 - AG \text{ (for dogs)}$$

$$SIG = [albumin] \times 4.58 - AG + 9 \text{ (for cats)}$$

Interpretation**Increased in**

- Acidosis caused by addition of unmeasured anions (lactic acidosis, ketoacidosis, renal failure, poisonings)
- Hyperphosphatemia (hyperphosphatemic acidosis)

Normal in

- Hyperchloremic acidosis

Decreased in

- Hypoalbuminemia (hypoalbuminemic alkalosis)
- SIG is not affected by changes in albumin concentration

Estimation of Severity of Strong Ion Difference Alkalosis and Acidosis Caused by Chloride changes**Chloride gap**

$$[Cl^-]_{gap} = 110 - [Cl^-] \times 146 / [Na^+] \text{ (for dogs)}$$

$$[Cl^-]_{gap} = 120 - [Cl^-] \times 156 / [Na^+] \text{ (for cats)}$$

Sodium-chloride difference

$$Na - Cl = [Na^+] - [Cl^-]$$

Only valid if $[Na^+]$ is normal

Interpretation**Increased in**

- Hypochloremic alkalosis

Normal in

- Hypoalbuminemic alkalosis

Decreased in

- Hyperchloremic acidosis

Identifying the Origin of Hypoxemia in Respiratory Acid-Base Disorders**Alveolar-arterial oxygen gradient**

$$(A-a) O_2 \text{ gradient} = 150 - 1.25 P_{CO_2} - PO_2$$

Interpretation (in hypoxemic patients)**Increased in**

- Pulmonary disease (e.g.; ventilation-perfusion inequality, right-to-left shunt)

Normal in

Alveolar hypoventilation (e.g.; central alveolar hypoventilation, abnormality in chest wall or respiratory muscles)

β -hydroxybutyrate, strong anions of renal failure) and weak (e.g., phosphate). The AG also is used to differentiate between hyperchloremic (normal AG) and high-AG metabolic acidoses. The AG in normal dogs and cats is mostly a result of the net negative charge of proteins and thus is heavily influenced by protein concentration, especially albumin. At plasma pH of 7.4 in dogs, each

decrease of 1 g/dl in albumin concentration is associated with a decrease of 4.1 mEq/L in the AG (Constable and Stämpfli, 2005). The SIG is not affected by changes in albumin concentration, and an increase in unmeasured strong anions is suspected whenever SIG is less than -5 mEq/L. The SIG has not been clinically tested in dogs and cats, but its derivation is sound, and it is superior to the AG to detect increases in unmeasured strong anions in other species.

Chloride Gap

Chloride is the most important extracellular strong anion. Increases in chloride lead to metabolic acidosis by decreasing SID, whereas decreases in chloride cause metabolic alkalosis by increasing SID. Therefore plasma Cl^- and HCO_3^- have a tendency to change in opposite directions in hypochloremic alkalosis and hyperchloremic acidosis. The contribution of Cl^- to changes in BE and HCO_3^- can be estimated by calculating the *chloride gap* (see Box 10-2). Chloride gap values greater than 4 mEq/L are associated with hypochloremic alkalosis, whereas values less than -4 mEq/L are associated with hyperchloremic acidosis. Whenever sodium concentration is normal, the *difference between the sodium and chloride concentrations* ($[Na^+] - [Cl^-]$) can be used. Normally $[Na^+] - [Cl^-]$ is approximately 36 mEq/L in dogs and cats. Values greater than 40 mEq/L are an indication of hypochloremic alkalosis, whereas values less than 32 mEq/L are associated with hyperchloremic acidosis.

Alveolar-Arterial Oxygen Gradient

Frequently patients with respiratory acidosis or alkalosis are also hypoxemic. When determining management options, it is important to differentiate between hypoxia from primary lung disease (e.g., ventilation-perfusion mismatching) and alveolar hypoventilation by calculating the alveolar-arterial oxygen gradient, or (A-a) O_2 gradient. Values less than 15 mm Hg generally are considered normal. If the (A-a) O_2 gradient is increased, a component of the hypoxemia results from ventilation-perfusion mismatching, although it may be increased in some patients with extrapulmonary disorders. Clinically a normal gradient excludes pulmonary disease and suggests some form of central alveolar hypoventilation or an abnormality of the chest wall or inspiratory muscles. To increase the specificity of the test to diagnose ventilation-perfusion mismatch, only patients with (A-a) O_2 gradient values more than 25 mm Hg should be considered abnormal (Johnson and de Moraes, 2006). These patients are likely to have primary pulmonary disease, but extrapulmonary disorders cannot be ruled out completely.

RESPIRATORY ACID-BASE DISORDERS**Disorders of P_{CO_2}**

Respiratory acid-base disorders are abnormalities in acid-base equilibrium initiated by a change in P_{CO_2} . The P_{CO_2} is regulated by respiration: a primary increase in P_{CO_2} acidifies body fluids and initiates the acid-base disturbance called respiratory acidosis, whereas a decrease in P_{CO_2} alkalizes body fluids and is known as respiratory alkalosis.

Respiratory Alkalosis

Respiratory alkalosis or primary hypocapnia is characterized by decreased P_{CO_2} , increased pH, and a compensatory decrease in HCO_3^- concentration in the blood. Respiratory alkalosis occurs whenever the magnitude of alveolar ventilation exceeds that required to eliminate the CO_2 produced by metabolic processes in the tissues. Common causes of respiratory alkalosis include stimulation of peripheral chemoreceptors by hypoxemia; primary pulmonary disease; direct activation of the brainstem respiratory centers; overzealous mechanical ventilation; and situations that cause pain, anxiety, or fear (Box 10-3). It is difficult to attribute specific clinical signs to respiratory alkalosis in the dog and cat. The clinical signs usually are caused by the underlying disease process and not by the respiratory alkalosis itself. However, in humans headache, light-headedness, confusion, paresthesias of the extremities, tightness of the chest, and circumoral numbness have been reported in acute respiratory alkalosis. If the pH exceeds 7.6 in respiratory alkalosis, neurologic, cardiopulmonary,

and metabolic consequences may arise. Such a pH only can be achieved in acute respiratory alkalosis before renal compensation ensues. Alkalemia results in arteriolar vasoconstriction that can decrease cerebral and myocardial perfusion. In addition, hyperventilation ($P_{CO_2} < 25$ mm Hg) causes decreased cerebral blood flow, potentially resulting in clinical signs such as confusion and seizures. Treatment of respiratory alkalosis should be directed at relieving the underlying cause of the hypocapnia; no other treatment is effective. Respiratory alkalosis severe enough to cause clinical consequences for the animal is uncommon. Hypocapnia itself is not a major threat to the well-being of the patient. Thus the underlying disease responsible for hypocapnia should receive primary therapeutic attention.

Respiratory Acidosis

Respiratory acidosis, or primary hypercapnia, results when carbon dioxide production exceeds elimination via the lungs. Respiratory acidosis almost always is a result of respiratory failure with resultant alveolar hypoventilation and is characterized by an increase in P_{CO_2} , decreased pH, and a compensatory increase in blood HCO_3^- concentration. Respiratory acidosis and hypercapnia can occur with any disease process involving the neural control of ventilation, mechanics of ventilation, or alveolar gas exchange resulting in hypoventilation, ventilation-perfusion mismatch, or both. Acute respiratory acidosis usually results from sudden and severe primary parenchymal (e.g., fulminant pulmonary edema), airway, pleural, chest wall, neurologic (e.g., spinal cord injury), or neuromuscular (e.g., botulism) disease. Chronic respiratory acidosis results in sustained hypercapnia and has many etiologies, including alveolar hypoventilation, abnormal respiratory drive, abnormalities of the chest wall and respiratory muscles, and increased dead space (Box 10-4).

Most clinical signs in animals with respiratory acidosis reflect the underlying disease process responsible for hypercapnia rather than the hypercapnia itself, and subjective clinical evaluation of the patient alone is not reliable in making a diagnosis of respiratory acidosis. In fact, patients with chronic, compensated respiratory acidosis may have very mild clinical signs. Neurologic signs may develop, particularly in acute hypercapnia, and seem to depend on the magnitude of hypercapnia, rapidity of change in CO_2 and pH, and amount of concurrent hypoxemia. Acute hypercapnia causes cerebral vasodilation, subsequently increasing cerebral blood flow and intracranial pressure. Clinically the CNS effects of hypercapnia can result in signs ranging from anxiety, restlessness, and disorientation to somnolence and coma, especially when P_{CO_2} approaches 70 to 100 mm Hg.

The most effective treatment of respiratory acidosis consists of rapid diagnosis and elimination of the underlying cause of alveolar hypoventilation. For example, airway obstruction should be identified and relieved, and medications that depress ventilation should be discontinued if possible. A patient breathing room air at sea level will develop life-threatening hypoxia ($PO_2 < 55$ to 60 mm Hg) before life-threatening hypercapnia. Thus supplemental oxygen and assisted ventilation are needed in treating acute respiratory acidosis. Although oxygen

Box 10-3

Principal Causes of Respiratory Alkalosis*

Hypoxemia (Stimulation of Peripheral Chemoreceptors by Decreased Oxygen Delivery)

- Right-to-left shunting
- Decreased P_{iO_2} (e.g., high altitude)

Ineffective Mechanical Ventilation (e.g., Inadequate Minute Ventilation, Improper CO₂ Removal)

*Modified from Johnson RA, de Morais HSA. Respiratory acid-base disorders. In: DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders*, ed 3, Philadelphia, 2006, Elsevier, p 283.

therapy may aid in the treatment of acute respiratory acidosis, oxygen may suppress the drive for breathing in patients with chronic hypercapnia. In chronic hypercapnia the central chemoreceptors become progressively insensitive to the effects of CO₂, and O₂ becomes the primary stimulus for ventilation. As a result, oxygen therapy may further suppress ventilation, worsening respiratory acidosis. If oxygen is administered, PO₂ should be kept between 60 and 65 mm Hg because the hypoxic drive to breathing remains adequate up to this level. When

mechanical or assisted ventilation is begun, care must be taken to decrease Paco₂ slowly. A sudden decrease in Pco₂ can result in cardiac arrhythmias, decreased cardiac output, and reduced cerebral blood flow. It can also lead to posthypercapnic metabolic alkalosis and rapid diffusion of CO₂ from cerebrospinal fluid into blood, thus quickly increasing cerebrospinal pH.

METABOLIC ACID-BASE DISORDERS**Disorders of A_{tot}**

Albumin, globulins, and inorganic phosphate are nonvolatile weak acids and collectively are the major contributors to A_{tot}. Changes in their concentrations directly change pH and HCO₃⁻. Common causes of A_{tot} acidosis and alkalosis are presented in Box 10-5.

Nonvolatile Buffer Ion Alkalosis

Hypoalbuminemic alkalosis. Hypoalbuminemic alkalosis is common in the critical care setting. In vitro a 1-g/dl decrease in albumin concentration is associated with an increase in pH of 0.093 in cats and 0.047 in dogs (Constable and Stämpfli, 2005). Presence of hypoalbuminemia complicates identification of increased

Box 10-5

unmeasured anions (e.g., lactate, ketoanions) because hypoproteinemia not only increases pH but also decreases AG. Thus the severity of the underlying disease leading to metabolic acidosis may be underestimated if the effects of hypoalbuminemia on pH, HCO_3^- , and AG are not considered. Treatment for hypoalbuminemic alkalosis should be directed at the underlying cause and the decreased colloid oncotic pressure.

Nonvolatile Buffer Ion Acidosis

Hyperphosphatemic acidosis. Hyperphosphatemia, especially if severe, can cause a large increase in A_{tot} , leading to metabolic acidosis. The contribution of phosphate to A_{tot} (and AG) can be estimated by multiplying the phosphate concentration in milligrams per deciliter by 0.58. Thus a phosphorus concentration of 5 mg/dl is equivalent to 2.88 mEq/L at a pH of 7.4. The most important cause of hyperphosphatemic acidosis is renal failure. Metabolic acidosis in patients with renal failure is multifactorial but mostly is caused by hyperphosphatemia and increases in unmeasured strong anions. Treatment for hyperphosphatemic acidosis should be directed at the underlying cause. Sodium bicarbonate administered intravenously shifts phosphate inside cells and may be used as adjunctive therapy in patients with severe hyperphosphatemic acidosis.

Disorders of Strong Ion Difference

Changes in SID usually are recognized by changes in HCO_3^- or BE from their reference values. It is important to understand that the change in SID from normal is equivalent to the change in HCO_3^- or BE from normal whenever the plasma concentrations of nonvolatile buffer ions (e.g., albumin, phosphate, globulin) are normal. A decrease in SID is associated with metabolic acidosis, whereas an increase in SID is associated with metabolic alkalosis. There are three general mechanisms by which SID can change (Table 10-2): (1) a change in the free water content of plasma; (2) a change in Cl^- ; and (3) an increase in the concentration of other strong anions.

Table 10-2

Mechanisms for Strong Ion Difference Changes*

Disorder	Mechanism	Clinical Recognition
SID Acidosis		
↓ In strong cations	↑ Free water (↓ sodium)	Dilutional acidosis
↑ In strong anions	↑ Chloride	Hyperchloremic acidosis
↑ Unmeasured strong anions		Organic acidosis
SID Alkalosis		
↑ In strong cations	↓ Free water (↑ sodium)	Concentration alkalosis
↓ In strong anions	↓ Chloride	Hypochloremic alkalosis

*From de Morais HSA, Constable PD: Strong ion approach to acid-base disorders. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders*, ed 3, Philadelphia, 2006, Elsevier, p 310.

Strong Ion Difference Alkalosis

There are two general mechanisms by which SID can increase, leading to metabolic alkalosis: an increase in Na^+ or a decrease in Cl^- . Strong cations other than sodium are tightly regulated, and changes of a magnitude that could affect SID clinically either are not compatible with life or do not occur. Conversely, chloride is the only strong anion present in sufficient concentration to cause an increase in SID when its concentration is decreased. Common causes of SID alkalosis are presented in Box 10-6.

Concentration alkalosis. Concentration alkalosis develops whenever a deficit of water in plasma occurs and is recognized clinically by the presence of hypernatremia or hyperalbuminemia. Solely decreasing the content of water increases the plasma concentration of all strong cations and strong anions and thus increases SID. Therapy for concentration alkalosis should be directed at treating the underlying cause responsible for the change in Na^+ . If necessary, serum Na^+ concentration and osmolality should be corrected.

Hypochloremic alkalosis. When water content is normal, SID changes only as a result of changes in strong anions and can only increase with a decrease in Cl^- . Hypochloremic alkalosis may be caused by an excessive loss of chloride relative to sodium or by administration of substances containing more sodium than chloride compared with normal extracellular fluid composition (see Box 10-6). The goal of treatment of metabolic alkalosis is to replace the chloride deficit while providing sufficient potassium and sodium to replace existing deficits, thus correcting the SID. Renal Cl^- conservation is enhanced in hypochloremic states, and renal Cl^- resorption does not return to normal until plasma Cl^- concentration is restored to normal or near normal. Dehydrated patients should be rehydrated accordingly. The SID can be corrected with a solution containing adequate amounts

Box 10-6

Principal Causes of Strong Ion Difference Alkalosis in Dogs and Cats

Concentration Alkalosis (↓ in Free Water: Recognizable by ↑ Na^+)

- Pure water loss
 - Inadequate access to water (water deprivation)
 - Diabetes insipidus
- Hypotonic fluid loss
 - Vomiting
 - Nonoliguric renal failure
 - Postobstructive diuresis

Hypochloremic Alkalosis (↓ Cl^- corrected)

- Excessive gain of sodium relative to chloride
 - Sodium bicarbonate administration
- Excessive loss of chloride relative to sodium
 - Vomiting of stomach contents
 - Therapy with thiazides or loop diuretics

*From de Morais HSA, Constable PD: Strong ion approach to acid-base disorders. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders*, ed 3, Philadelphia, 2006, Elsevier, p 310.

of chloride (e.g., 0.9% NaCl, lactated Ringer's solution, KCl-supplemented fluids). In cases in which expansion of extracellular volume is desired, intravenous infusion of 0.9% NaCl is the treatment of choice.

SID Acidosis

Three general mechanisms can cause SID to decrease, resulting in SID acidosis: (1) a decrease in Na^+ ; (2) an increase in Cl^- ; and (3) an increased concentration of other strong anions (e.g., l-lactate , $\beta\text{-hydroxybutyrate}$). Common causes of SID acidosis are presented in Box 10-7.

Dilutional acidosis. Dilutional acidosis occurs whenever there is an excess of water in plasma and is recognized clinically by the presence of hyponatremia. Increasing the water content of plasma decreases the concentration of all strong cations and strong anions and thus SID. Large increases in free water are necessary to cause an appreciable decrease in SID. It has been estimated that in dogs and cats a decrease in serum Na^+ concentration by 20 mEq/L is associated with a 5 mEq/L decrease in BE (de Moraes and Leisewitz, 2006). Therapy for dilutional acidosis should be

Box 10-7

Principal Causes of Strong Ion Difference Acidosis in Dogs and Cats

Dilution Acidosis (\uparrow in Free Water: Recognizable by $\downarrow [\text{Na}^+]$)

- With hypervolemia (gain of hypotonic fluid)
 - Severe liver disease
 - Congestive heart failure
 - Nephrotic syndrome
- With normovolemia (gain of water)
 - Psychogenic polydipsia
 - Hypotonic fluid infusion
- With hypovolemia (loss of hypertonic fluid)
 - Vomiting
 - Diarrhea
 - Hypoadrenocorticism
 - Third-space loss
 - Diuretic administration

Hyperchloremic Acidosis ($\uparrow [\text{Cl}^-]$ Corrected)

- Excessive loss of sodium relative to chloride
 - Diarrhea
- Excessive gain of chloride relative to sodium
 - Fluid therapy (e.g., 0.9% NaCl, 7.2% NaCl, KCl-supplemented fluids)
 - Total parenteral nutrition
- Chloride retention
 - Renal failure
 - Hypoadrenocorticism

Organic Acidosis (\uparrow Unmeasured Strong Anions)

- Uremic acidosis
- Diabetic ketoacidosis
- Lactic acidosis
- Toxicities
 - Ethylene glycol
 - Salicylate

*From de Moraes HSA, Constable PD: Strong ion approach to acid-base disorders. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders*, ed 3, Philadelphia, 2006, Elsevier, p 310.

directed at the underlying cause of the change in Na^+ . If necessary, serum Na^+ concentration and osmolality should be corrected.

Hyperchloremic acidosis. Increases in $[\text{Cl}^-]$ can decrease SID substantially, leading to so-called hyperchloremic acidosis. Hyperchloremic acidosis may be caused by chloride retention (e.g., early renal failure, renal tubular acidosis), excessive loss of sodium relative to chloride (e.g., diarrhea), or administration of substances containing more chloride than sodium compared with normal extracellular fluid composition (e.g., administration of KCl, 0.9% NaCl). Treatment of hyperchloremic acidosis should be directed at correction of the underlying disease process. Special attention should be given to plasma pH. Bicarbonate therapy can be instituted whenever plasma pH is less than 7.2.

Organic acidosis. Accumulation of metabolically produced organic anions (e.g., l-lactate , acetoacetate, citrate, $\beta\text{-hydroxybutyrate}$) or addition of exogenous organic anions (e.g., salicylate, glycolate from ethylene glycol poisoning, formate from methanol poisoning) causes metabolic acidosis because these strong anions decrease SID. Accumulation of some inorganic strong anions (e.g., SO_4^{2-} in renal failure) will resemble organic acidosis because these substances decrease SID. The most frequently encountered causes of organic acidosis in dogs and cats are renal failure (uremic acidosis), diabetic ketoacidosis, lactic acidosis, and ethylene glycol toxicity. Management of organic acidosis should be directed at stabilization of the patient and treatment of the primary disorder. Patients with severe acidosis ($\text{pH} < 7.1$) and renal failure may benefit from small, titrated doses of NaHCO_3 . The efficacy of NaHCO_3 therapy in renal failure is related partly to the shift of phosphate inside the cell with consequent amelioration of the hyperphosphatemic acidosis. Sodium bicarbonate should be used cautiously because metabolism of accumulated organic anions normalizes SID and increases HCO_3^- . Treatment of lactic acidosis is controversial, and sodium bicarbonate administration is not likely to help patients with lactic acidosis. Tissue hypoxia is considered to be the most likely underlying problem in lactic acidosis. Thus therapeutic measures should be taken to augment oxygen delivery to the tissues and reestablish cardiac output. Sodium bicarbonate also is not indicated in ketoacidotic diabetic patients even if pH is less than 7.0 because NaHCO_3 administration is associated with deleterious effects in humans with ketoacidosis (Okuda et al., 1996; Viallon et al., 1999). Sodium bicarbonate is usually not necessary in such settings because the acidosis improves rapidly with appropriate management using fluid resuscitation, insulin, and correction of potassium deficits (Gauthier and Szerlip, 2002).

CHAPTER 11

Colloid Fluid Therapy

ELKE RUDLOFF, *Glendale, Wisconsin*
REBECCA KIRBY, *Glendale, Wisconsin*

Severe intravascular volume depletion associated with conditions such as hemorrhage, trauma, systemic inflammatory response syndrome (SIRS) diseases, and various metabolic diseases ultimately results in poor tissue perfusion, tissue hypoxia, and cellular energy depletion. Loss of vascular tone and increased capillary permeability can be a consequence and cause maldistribution of fluid between the fluid compartments. Timely and appropriate intravascular fluid resuscitation becomes the mainstay of treatment.

The goals of resuscitation and maintenance fluid therapy in the critically ill animal are to restore and maintain perfusion and hydration without causing volume overload and complications caused by pulmonary, peripheral, and brain edema. By using colloid fluids in conjunction with crystalloid fluids, goal-driven resuscitation (also known as end-point resuscitation) can be achieved more rapidly and with less fluid volume. Maintaining an effective circulating volume can be challenging when there is vascular leakage, vasodilation, excessive vasoconstriction, inadequate cardiac function, hypoalbuminemia, or ongoing fluid loss. Whether a fluid administered intravenously remains in the intravascular compartment or moves into the interstitial or intracellular spaces depends on the dynamic forces that affect fluid movement between body fluid compartments.

FLUID DYNAMICS

The body fluids are distributed between three major compartments (intracellular, interstitial, and intravascular). The cellular membrane defines the intracellular space

and is freely permeable only to water. Most ions must enter the cell by specific mechanisms such as channels, solvent drag, carriers, or pumps. Intracellular ions help retain water within the cell by osmosis. The intravascular space is contained within a vascular semipermeable “membrane” composed of a single thin layer of endothelium resting on collagen and fibrin. Fluid and nutrient exchanges between the blood and the tissues occur primarily at the level of the capillary membrane. Larger molecules such as the plasma proteins (albumin, fibrinogen, and globulins) are too large to freely cross this semipermeable membrane.

The Starling-Landis equation defines the forces that control the rate of the flow of fluid between the capillary and interstitium:

$$V = k [(HP_c - HP_i) - \sigma (COP_c - COP_i)] - Q$$

where V = filtered volume, k = filtration coefficient, HP = hydrostatic pressure, c = capillary, i = interstitial fluid, sigma = membrane pore size, COP = colloid osmotic pressure, and Q = lymph flow

The main components that control intravascular fluid volume include intravascular colloid osmotic pressure (COP) and hydrostatic pressure (HP) (Fig. 11-1). Eighty percent of the COP is produced by albumin, which is the most abundant extracellular protein. The pressure generated by albumin is augmented by its negative charge, which attracts cations (e.g., sodium) and water. This unique property is termed the *Donnan effect*. Capillary membrane pore size and the filtration coefficient control

Fig. 11-1 The main components of the Starling-Landis equation that affect intravascular water content include intravascular hydrostatic pressure (HP) and colloid osmotic pressure (COP). The intravascular HP is a result of intravascular volume, cardiac output (CO), and systemic vascular resistance (SVR). Under normal conditions the HP favors the movement of fluid from the vessel into the interstitium. The COP is the force that opposes intravascular hydrostatic pressure, supporting intravascular water retention. The COP is generated by the presence of large molecules (primarily proteins) that do not readily pass the capillary membrane and create an osmotic effect.

the ease with which these larger molecules leave the intravascular space. The size of the pore varies from tissue to tissue (e.g., tight junctions in the brain and large intercellular gaps in the liver). The filtration coefficient has been found to be variable and partly dependent on the amount of albumin in the intravascular space.

The dynamics of normal fluid movement across the capillary membrane can change with certain diseases. Fluid will move from the intravascular into the interstitial or third-space compartment under certain conditions (Fig. 11-2, Table 11-1). Plasma COP can increase with water loss (hemoconcentration), remain the same when there is acute volume depletion, or decrease with protein loss. In addition to capillary dynamics, the composition of intravenously administered fluids will determine how these fluids are distributed between fluid compartments.

BASIC COLLOID FLUID PHARMACOLOGY

The composition of intravenous fluids determines how these fluids are distributed between interstitial and intravascular fluid compartments. The two major categories of intravenous fluids are crystalloids and colloids. A crystalloid fluid is a water-based solution with small molecules permeable to the capillary membrane. A colloid fluid is a crystalloid-based solution containing large molecules that are impermeable to normal capillary membranes. When large volumes are needed for intravascular fluid resuscitation, crystalloids alone may fail to provide effective

Fig. 11-2 Fluid can pass out of the intravascular space under several conditions listed in Table 11-1: increased hydrostatic pressure (HP), increased capillary permeability, decreased filtration coefficient, and decreased colloid osmotic pressure (COP). These conditions lead to the consequences of peripheral edema and hypovolemia.

Table 11-1

Examples of Conditions That Result in Movement of Fluid Out of the Intravascular Space

Condition	Example
Plasma to interstitial HP gradient increases over the COP gradient	Hypertension Fluid overload
Capillary membrane pore size becomes larger	SIRS-associated diseases <ul style="list-style-type: none"> • Pancreatitis • Peritonitis • Pyometra • Sepsis • Severe gastroenteritis • Burns • Multitrauma • Vasculitis
The filtration coefficient changes	Burns
Intravascular COP falls below interstitial COP	Hypoalbuminemia Hypoalbuminemia <ul style="list-style-type: none"> • SIRS disease • Liver dysfunction • Protein-losing nephropathy/enteropathy

COP, Colloid osmotic pressure; HP, hydrostatic pressure; SIRS, systemic inflammatory response syndrome.

intravascular volume support without causing interstitial volume overload with edema.

Ultimately the selection of a colloid or a combination of colloids for intravenous resuscitation and maintenance is based on the pharmacology of the fluid and the disorder requiring treatment. Each colloid solution is unique, and knowledge of the composition and pharmacology of the fluid is needed to make an appropriate colloid selection for a specific patient (see Table 11-2). It is the difference in macromolecular structure and weight that dictates the colloid osmotic effect, method of excretion, and half-life of the colloid solution. The more small molecules per unit volume of colloid, the greater is the initial colloid osmotic effect and plasma volume expansion. When the number of large molecules per unit volume of colloid is high, the colloid is retained longer within the vascular space.

Solutions that contain naturally produced proteins such as albumin (whole blood, plasma products, and concentrated human albumin solutions) or hemoglobin (hemoglobin-based oxygen carriers [HBOCs]) are referred to as natural colloids. Solutions that contain synthetically derived colloid particles such as dextrans (dextran 70) and hydroxyethyl starches (HESs) (hetastarch and pentastarch) are referred to as synthetic colloids.

Large-volume fluid resuscitation decreases the concentration of coagulation proteins in the plasma and can cause a dilutional coagulopathy. Synthetic colloids are not a substitute for blood products when albumin, hemoglobin, antithrombin, or coagulation proteins are needed.

ALBUMIN

Albumin, the most abundant colloid molecule in plasma, can be administered through plasma transfusions or concentrated (25%) human albumin. Frozen plasma and fresh frozen plasma contain approximately 5% albumin, whereas whole blood contains approximately 2.5% albumin. The size of the albumin molecule is constant, and the higher the concentration of albumin, the greater is the colloid osmotic effect per milliliter of solution. Plasma transfusions have an albumin concentration equal to that of plasma and may not add significantly to the intravascular COP when administered as the sole colloid. Because of its high concentration of albumin and high COP (200 mm Hg), 25% human albumin has the greatest capability of increasing plasma COP. When capillary permeability is normal, 25% albumin can be an effective colloid for rapid intravascular volume expansion. It can also be used to minimize interstitial edema in animals with hypoalbuminemia caused by inadequate albumin production or renal and gastrointestinal albumin loss. However, when increased capillary permeability allows plasma albumin to pass into the interstitium, the initial intravascular COP benefits of albumin infusion will be temporary and will likely lead to increased interstitial COP and edema.

Immunologic reactions are a risk with allogenic blood product transfusions. Human albumin has physiochemical properties that differ from canine and feline albumin, and complications appear to occur at a higher rate (about 20%) with human albumin administration in dogs than

Table 11-2

Characteristics of Colloid Fluids

Colloid	Osmolarity (mOsm/L)	pH	Na+ (mEq/L)	Cl- (mEq/L)	K+ (mEq/L)	Mg++ (mEq/L)	Ca++ (mEq/L)	Dextrose (g/L)	Buffer	COP (mm Hg)	Miscellaneous

COP, Colloid osmotic pressure.

with allogenic transfusions. Acute and delayed immune-mediated reactions have been reported after the administration of both human albumin and allogenic plasma and blood transfusions, requiring vigilant monitoring for allergic reactions. These colloids are administered slowly for the first hour, with careful monitoring for adverse reactions, before increasing to standard recommended rates of infusion.

HEMOGLOBIN-BASED OXYGEN CARRIERS

HBOC solutions bind with oxygen and transport it to the tissues where it is distributed to the cells. Because the solution is stroma free, it is able to pass through the microcirculation that might not allow the passage of red blood cells. The colloidal properties, oxygen-carrying capacity, and low antigenicity may make HBOC solutions an ideal fluid to administer to animals with severe anemia, hypotension, and/or hypovolemia.

Oxyglobin (Biopure), a stroma-free hemoglobin, is an ultrapure bovine-origin polymerized hemoglobin solution approved by the Food and Drug Administration for therapeutic use in dogs with anemia. Oxygen is bound to hemoglobin by a chloride-dependent process, facilitating its release at the capillary. In addition to acting as a temporary oxygen-carrying substitute for red blood cells, it maintains osmotic pressure and has a vasoconstricting effect that can reduce the volume required for resuscitation. It can be stored at room temperature with a 3-year shelf life if unopened, making it more easily available and transportable than blood transfusions. It has universal compatibility and is unlikely to transmit hematogenous diseases. It is excreted in the urine and bile. Its limitations include a short half-life (40 hours) once administered, interference with enzyme-based chemistry analyses, and requirements for red blood cell replacement if significant anemia is present. Side effects occur most commonly in euvoletic patients and include pulmonary edema, vomiting and diarrhea, and hypertension, requiring slow administration in small quantities, titrated to effect.

DEXTRAN 70

Dextran is a polysaccharide composed of linear glucose residues. These compounds are produced by the enzyme dextran sucrose during the growth of various strains of the bacterium *Leuconostoc* in media containing sucrose. Different molecular-weight dextrans can be produced by acid hydrolysis of the parent macromolecule. The development of acute renal failure is rare with dextran 70 in contrast to dextran 40.

Retained dextran 70 molecules are enzymatically metabolized by dextrinase to glucose in the liver and may increase serum glucose values. Having a molecular weight similar to albumin, dextran 70 molecules will diffuse into the interstitium when there is increased capillary permeability. At recommended doses dextran 70 can interfere with fibrin clot strength, reduce factor VIII and von Willebrand's factor, and affect platelet function. Partial thromboplastin and prothrombin times were prolonged in dogs reported to have received therapeutic doses of dextran 70. Its use

in animals undergoing surgery or with coagulation abnormalities should be with extreme caution.

Allergic reactions have not been reported in the dog or cat. Serum bilirubin concentration can be increased for unknown reasons. The presence of dextran 70 in the circulation may cause a change in the total solids value obtained via refractometry, not reflecting actual protein content (Bonagura, 1995). In addition, red blood cell cross-linking occurs with dextran 70 and appears as rouleaux formation, potentially interfering with blood typing and crossmatching.

HYDROXYETHYL STARCH

HES, the parent name of a synthetic polymer of glucose (98% amylopectin), is made from a waxy species of either plant starch maize or sorghum. It is a highly branched polysaccharide closely resembling glycogen, formed by the reaction between ethylene oxide and amylopectin in the presence of an alkaline catalyst. The molecular weight and molar substitution can be adjusted by the degree of substitution of hydroxyl groups with hydroxyethyl groups at the C2, C3, and C6 positions on the glucose molecule. The greater the substitution on position C2 in relation to C6 (C2:C6 ratio), the slower the degradation of the molecule by amylase. Renal function has been shown to decline after infusion of hetastarch with molar substitutions greater than 0.62 in humans undergoing surgery, a characteristic that has not been identified in animals. Renal effects of lower molar substitution solutions have not been evaluated.

The number-averaged molecular weight (M_n) is the arithmetic mean of the molecular weights of the polymers in solution. Weight-averaged molecular weight (M_w) is the sum of the number of molecules at each M_n divided by the total of all molecules. This weight is generally larger when larger polymers are present in solution.

The classification of different HES products includes the ratio of the M_w to the proportion of substitution. There are two HES products clinically available in the United States at this time: hetastarch and pentastarch. Hetastarch can be purchased in 0.9% sodium chloride (Hespan, Baxter; M_w of 450 kD and 0.7 degree of substitution) or in lactated Ringer's solution (Hextend, BioTime, Inc; a M_w of 670 kD and 0.75 degree of substitution). The use of Hextend may be associated with fewer coagulation abnormalities when compared to 6% hetastarch in saline because it contains calcium, which can become depleted in coagulopathic states. The electrolyte and buffer compositions of Hextend may reduce the incidence of hyperchloremic acidosis. Hextend also contains 0.45 mmol/L of magnesium and 99 mg/dl (0.99%) of dextrose. Pentastarch (Pentaspas, B. Braun McGaw) is a 10% solution that has a lower molecular weight than hetastarch (M_w of 264 kD and 0.7 degree of substitution).

Although HES can affect von Willebrand's factor and factor VIII function, it is not as significant as with dextran 70. Clinical evidence of bleeding has not been reported in animals receiving HES 450/0.7 at doses up to 20 ml/kg/day. However, we have experienced prolongation in activated clotting times (ACTs) less than 50% above normal at this dosage. An elevation in ACT above 50% of the normal reference range warrants investigation for concurrent coagulation problems. An HES product available in Europe,

Voluven (Fresenius Kabi), has a M_w of 130 kD and a 0.4 degree of substitution. The reduced M_w and molar substitution reduce the risk of coagulation side effects, and an increased C2:C6 ratio prolongs half-life. HES 130/0.4 doses have been recommended up to 50 ml/kg.

A differential charge may exist between administered HES molecules and the capillary pore, blocking the passage of HES molecules into the interstitium. This property is independent of molecular size. HES may also down-regulate and decrease expression of endothelial surface adhesion molecules, which has been reported to decrease inflammation, endothelial injury, and leukocyte migration into the interstitium. HES has been shown to reverse changes in microvascular permeability caused by oxygen-free radicals during reperfusion injury. This can explain why HES molecules remain in the vascular space in the septic patient when albumin does not (Marx et al., 2002).

Smaller HES molecules are filtered through the glomerulus and excreted in the urine, excreted through the bile, or passed into the interstitium and ingested by macrophages. Larger molecules are degraded by α -amylase into smaller HES molecules. Hetastarch has been reported as nontoxic and nonallergenic in doses up to 100 ml/kg in dogs (Ballinger, Solanke, and Thompson, 1966). The authors have observed signs of nausea, occasional vomiting, and hypotension with rapid infusion of hetastarch in the cat. Slow administration of small-volume increments has eliminated these side effects in cats.

CLINICAL USE

Goals for colloid administration are to improve intravascular volume and systemic blood flow while maintaining intravascular COP. Selection of a specific colloid or colloids is based on individual traits of the colloid and the disease process of the animal (Tables 11-2 and 11-3).

When capillary permeability is normal, hetastarch, dextran 70, and 25% human albumin are effective for

expanding intravascular volume while minimizing interstitial edema. However, perfusion problems caused by SIRS are associated with increased capillary pore size and hypovolemia (see Fig. 11-2). An intravenous colloid solution should be administered that is larger than the pore size in the capillary membrane. When hypoalbuminemia is a prominent feature, HES is the colloid of choice. Human albumin is usually reserved for use in severely hypoalbuminemic animals with normal capillary permeability.

Dextran 70 is used with extreme caution in animals with coagulation abnormalities. If large volumes of HES are required to restore perfusion, plasma or whole blood transfusions may be required to supplement coagulation proteins and restore clotting times. Oxyglobin is selected when there is a need to improve tissue oxygenation associated with maldistribution of blood flow or anemia. Blood component transfusions are an option when anemia and/or coagulopathies exist.

Based on the disease process and resuscitation needs, a single colloid or a combination of colloids is selected to obtain the desired benefits. Colloids are typically administered in combination with isotonic crystalloids, allowing the crystalloid volume for intravascular volume replacement to be decreased by 40% to 60% of the amount calculated for crystalloid resuscitation alone. When more than one type of colloid is needed, the colloids are usually administered consecutively rather than simultaneously. Dogs can tolerate rapid intravenous infusion of synthetic colloids for immediate intravascular resuscitation. In the cat all forms of colloid are administered more slowly (over 5 to 15 minutes).

The volume of fluids to administer for resuscitation is directed toward achieving desired clinical end-point parameters (heart rate, blood pressure, central venous pressure, pulmonary capillary wedge pressure, pulses, and capillary refill time), described as early goal-directed therapy in humans and end-point or goal-oriented resuscitation in animals. The objective is to infuse the least amount of fluids necessary to achieve and maintain end-point perfusion

Table 11-3

Colloid Choices and Resuscitation Goals Used Based on Hypovolemic Condition in the Dog*

Condition	Resuscitation Colloid	Resuscitation Goal
Hypovolemic and/or traumatic shock	HES Dextran 70 Oxyglobin	MAP 60–80 mm Hg [†] HR normal CVP 8–10 cm H ₂ O
Trauma or edema in the brain or lungs	HES Dextran 70 Oxyglobin	MAP 60 mm Hg HR <140 beats/min CVP 5–8 cm H ₂ O
Hypovolemic shock with hemorrhage	Oxyglobin Whole blood pRBC + HES/dextran 70	MAP 60 mm Hg HR <140 beats/min CVP 5–8 cm H ₂ O
Hypovolemic heart failure in a critically hypotensive animal	HES	MAP 60 mm Hg HR < 180 beats/min
Hypovolemia in the chronically hypoalbuminemic animal	HES 25% Human albumin	MAP 60–80 mm Hg HR normal CVP 8–10 cm H ₂ O

[†]Systolic arterial pressure >90 mm Hg.

parameters for the condition being treated. End-point perfusion parameters to achieve with most clinical conditions will be within high normal or supranormal ranges. When the patient is at risk for heart failure, hemorrhage, or brain or lung edema, low normal end points are selected to avoid exacerbation of hemorrhage or edema.

When low normal resuscitation end points are the goal, replacement isotonic crystalloids are administered initially (10 to 15 ml/kg) with HES or dextran 70 (3- to 5-ml/kg increments) titrated to effect (up to 20 ml/kg). When high normal or supranormal end points are desired, larger volumes of replacement isotonic crystalloids can be administered initially (20 to 40 ml/kg) with HES or dextran 70 at larger volumes (10 to 15 ml/kg) titrated as needed (up to 30 ml/kg). If 25% human albumin is used for acute volume resuscitation, up to 4 ml/kg has been used as a slow bolus infusion (Mathews and Barry, 2005).

Hypothermia, hypotension, and bradycardia are typical clinical findings in the cat in hypovolemic shock. Hypothermia perpetuates hypotension and must be rapidly corrected as part of the resuscitation plan to prevent fluid overload. Initially replacement isotonic crystalloids are administered (10 to 15 ml/kg), and HES or dextran 70 (3 to 5 ml/kg) titrated to reach a systolic indirect peripheral blood pressure higher than 40 mm Hg. Maintenance crystalloids and colloids are given at this time while aggressive external warming is provided to bring the rectal temperature above 98° F (within 30 minutes). It is common for the arterial blood pressure and heart rate to reach desired end points after warming is achieved without the administration of additional resuscitation fluids. However, additional crystalloid and colloid doses can be administered if blood pressure remains suboptimal despite warming, assuming the underlying disorder is volume related and not the result of cardiogenic shock.

Bolus infusions of colloids are titrated in succession, and clinical parameters assessed in between boluses until end-point parameters are achieved. When large volumes are required to reach resuscitation end points, coagulation parameters are closely monitored, and coagulation factors replaced as needed. Once the resuscitation goal has been achieved, a continuous-rate infusion (CRI) of HES or dextran 70 (20 to 30 ml/kg/day) or Oxyglobin (cat: 10 ml/kg/day; dog: 30 ml/kg/day) can be used to maintain the intravascular COP until the capillaries restore their integrity and recovery is eminent. Crystalloids are administered simultaneously to restore and maintain hydration and replacement of ongoing losses.

When end-point parameters have not been reached despite adequate fluid replacement, causes of nonresponsive shock need to be examined for, and vasoactive agents considered. Oxyglobin has a vasoconstricting effect and can be used in situations resulting in persistent vasodilation. When Oxyglobin is used in the dog for its vasoconstricting properties, 5-ml/kg incremental infusions are given to reach desired end points (to a total of 30 ml/kg). We have used Oxyglobin, 1- to 3-ml incremental infusions in hypertensive cats, administered slowly to effect (up to 10 ml/kg) and have found that this slow titration reduces the risk of acute volume overload and pulmonary

edema. An Oxyglobin CRI is then initiated to maintain the blood pressure along with crystalloids for maintenance of hydration and ongoing losses.

A critical animal that is receiving crystalloids may benefit from intravascular colloid support but does not require aggressive intravascular volume resuscitation. The daily dose of HES or dextran 70 (20 ml/kg) can then be administered over 2 to 4 hours by CRI, decreasing the amount of crystalloid infused during this period. When there is normal capillary permeability and albumin replacement is desired, 25% human albumin can be infused as a CRI (1 to 4 ml/kg over 12 to 72 hours). Plasma is administered when there is need for albumin, coagulation factors, and/or antithrombin. The dose of plasma is variable, with an end-point goal of maintaining and/or improving albumin, coagulation factor, and antithrombin concentrations. The rate of plasma infusion is calculated to maximize volume infusion without causing fluid overload.

Perfusion and hydration parameters are closely monitored during and after colloid infusion. Early clinical signs of fluid intolerance include serous nasal discharge, chemosis, tachypnea, dull lung sounds (pleural effusion), "moist" lung sounds or crackles (pulmonary edema), and gelatinous subcutaneous swelling (peripheral edema). Signs of allergic reaction include facial swelling, urticaria, abrupt hypotension, tachycardia, nausea, vomiting, fever, and hyperemia. Monitoring for acute allergic reaction and anaphylaxis is more important in patients receiving transfusions and concentrated albumin.

CHAPTER 12

Acute Abdomen: Evaluation and Emergency Treatment

F. ANTHONY MANN, *Columbia, Missouri*

Acute abdomen may be defined as the acute onset of abdominal pain necessitating prompt diagnosis and immediate medical or surgical intervention to prevent deterioration of the patient. Because many of the conditions responsible for acute abdomen may progress to a state of shock, abdominal pain may not be evident at the time the animal is presented for medical attention.

CLINICAL SIGNS

Abdominal pain may be manifested as peculiar posture such as the praying position. In the praying position the animal lies in sternal recumbence with the pelvic limbs in standing position to elevate the pelvis and caudal abdomen. Animals may also exhibit abdominal pain by a reluctance to move; by ambulating in a stilted gait; or by taking short, careful steps. Abdominal tenderness may be noted by an avoidance reaction, vocalization, or guarding ("splinting") when the abdomen is touched. Some animals with acute abdomen may become apprehensive in anticipation of abdominal contact. Nausea exhibited through hypersalivation may be apparent as a result of abdominal pain. Other clinical signs are related to the underlying cause of the acute abdomen, such as protracted vomiting from pancreatitis, fever caused by septic peritonitis, hemorrhagic diarrhea resulting from canine parvoviral enteritis, and pale mucous membranes caused by traumatic hemoabdomen.

DIFFERENTIAL DIAGNOSES

Differential diagnoses of disorders that may lead to the development of acute abdomen are listed in Table 12-1.

Some of these causes have obvious surgical or medical indications, whereas others require some decision making based on the individual situation. Many patients with acute abdomen have serious diseases that require prompt attention to patient status and appropriate stabilization measures before a definitive diagnosis can be achieved and specific therapy implemented.

INITIAL PATIENT MANAGEMENT

On presentation the patient with an acute abdomen should have a rapid primary survey to ascertain immediate needs and determine priorities in diagnostics and therapeutics. The primary survey should include an abbreviated physical examination with emphasis on mental, respiratory, and cardiovascular status. Severely depressed animals with abnormal breathing and altered (weak or bounding) peripheral pulses should be interpreted to be in (or progressing toward) shock and should have appropriate resuscitative measures before detailed diagnostics and definitive therapy (see other chapters in this section). Immediately before emergency treatment procedures (such as shock doses of intravenous fluids), blood and urine samples should be obtained for a minimal database.

DIAGNOSTIC TESTS

Signalment and History

Signalment and history can be helpful in shortening the list of differential diagnoses and arranging those remaining according to likelihood. For example, a miniature

Table 12-1

Differential Diagnosis for the Acute Abdomen

Body System Cause of Acute Abdomen	Treatment	Body System Cause of Acute Abdomen	Treatment
Gastrointestinal Digestive System		Reproductive System	
Gastric dilation	DS, PE	Female	
Gastric dilation-volvulus	DS, DE	Acute metritis	PS, PE
Gastroduodenal ulceration	NS	Pyometra	DS, DE
Gastroduodenal perforation	DS, PE	Uterine torsion	DS, DE
Gastroduodenal rupture	DS, DE	Dystocia	PS, PE
Gastroduodenal dehiscence	DS, DE	Uterine rupture	DS, DE
Gastroenteritis (viral, bacterial, toxic [i.e., garbage])	NS	Ovarian cyst	PS, PE
Hemorrhagic gastroenteritis	NS	Ovarian neoplasia	DS, PE
Intestinal obstruction (foreign body, intussusception, neoplasia)	DS, PE	Male	
Functional intestinal obstruction: ileus	NS	Acute prostatitis	NS
Intestinal ulceration	NS	Prostatic abscess	DS, PE
Intestinal perforation	DS, DE	Prostatic cysts	DS, PE
Intestinal rupture	DS, DE	Prostatic neoplasia	DS, PE
Intestinal dehiscence	DS, DE	Testicular torsion	DS, DE
Intestinal volvulus	DS, DE	Hematopoietic System: Spleen	
Cecal inversion	DS, PE	Splenic mass (hematoma, extramedullary hematopoiesis, neoplasia, nodular hyperplasia, abscess)	DS, PE
Obstipation	NS	Splenic rupture (mass)	DS, DE
Colitis	NS	Splenic rupture (trauma)	PS, PE
Colonic obstruction	NS	Splenic torsion	DS, DE
Colonic perforation	DS, DE	Peritoneum and Mesentery	
Colonic rupture	DS, DE	Peritonitis: septic	DS, DE
Colonic dehiscence	DS, DE	Peritonitis: chemical (bile, urine, pancreatic enzymes)	PS, PE
Hepatobiliary Digestive System		Parietal peritoneal trauma: blunt	NS
Acute hepatitis (toxic, infectious)	NS	Parietal peritoneal trauma: penetrating	DS, DE
Hepatic abscess	DS, PE	Mesenteric traction: large masses	DS, PE
Hepatic trauma	PS, PE	Mesenteric lymphadenopathy	PS, PE
Hepatic rupture	PS, PE	Mesenteric lymphadenitis	NS
Hepatobiliary neoplasia	PS, PE	Mesenteric volvulus	DS, DE
Biliary obstruction (calculi, neoplasia, pancreatitis, abscess)	PS, PE	Mesenteric avulsion	DS, DE
Biliary rupture	DS, DE	Mesenteric artery thrombosis	DS, DE
Cholecystitis	PS, PE	Adhesions with organ entrapment, internal hernias	DS, PE
Cholangiohepatitis	NS	Abdominal Wall	
Pancreatic Digestive System		Trauma	PS, PE
Acute pancreatitis	NS	Abscess	DS, PE
Pancreatic abscess	DS, PE	Hematoma	PS, PE
Urinary System		Strangulated hernias	DS, DE
Acute nephrosis (toxicosis)	NS		PS, PE
Acute nephritis-pyelonephritis	NS	Extraabdominal	
Urinary calculi: renal	PS, PE	Intervertebral disk disease	PS, PE
Urinary calculi: ureteral	PS, PE	Diskospondylitis	PS, PE
Urinary calculi: cystic	PS, PE	Toxicities (heavy metal)	NS
Urinary calculi: urethral	PS, PE	Thoracic wall disease	PS, PE
Trauma-avulsion-rupture (renal, ureteral, cystic, urethral)	DS, PE	Steatitis	NS
Obstruction (neoplasia, stricture): ureter	DS, PE	Myositis	NS
Obstruction (neoplasia, stricture): urethra	DS, PE	Hypoadrenocorticism	NS
Renal artery thrombosis	PS, PE		
Renal neoplasia	PS, PE		

DE, Definitely requires emergent surgery; DS, definitely surgical; NS, nonsurgical (the urgency of medical treatment depends on the specific problem and the condition of the animal; some nonsurgical acute abdomen cases may eventually require surgery on a nonemergent basis); PE, potentially requires emergent surgery (some conditions designated as PE may require surgery, although not on an emergent basis); PS, potentially surgical.

Box 12-1

Historical Information to be Included in Cases of Acute Abdomen

- Diet
- Appetite
- Weight change
- Water consumption
- Urination: characterize polyuria, anuria, pollakiuria
- Defecation, diarrhea: characterize frequency, presence of blood, color, volume, relation to meals
- Vomiting: characterize frequency, presence of blood, color, volume, relation to meals
- Exposure to toxins, trauma (blunt, penetrating), foreign body ingestion
- Previous disease
- Previous abdominal surgery
- Length of illness
- How quickly signs develop

schnauzer with acute abdominal pain is more likely to have acute pancreatitis than gastric dilation-volvulus. A history of dietary indiscretion in a well-vaccinated dog with no exposure to other dogs would prioritize garbage intoxication over parvoviral enteritis. A complete history should be taken, but certain questions should be emphasized in cases of acute abdomen as listed in Box 12-1.

Physical Examination

A complete body systems review is important for a full understanding of the patient's condition, but the patient's initial status may dictate that some aspects of the physical examination receive a low priority. Physical evaluation not directly related to the patient's immediate status can be postponed. The abdominal portion of the physical examination should be performed in each case of acute abdomen. However, the abdominal evaluation should be the last part of the physical examination for two reasons: (1) serious extraabdominal abnormalities may otherwise be overlooked; and (2) manipulation of a tender abdomen may elicit pain and apprehension that could interfere with further evaluation.

Physical examination of the abdomen should include visual inspection, auscultation, percussion, ballottement, superficial and deep palpation, and digital rectal palpation. The examination should proceed from the least to most likely technique to elicit a pain response. Abnormalities that may be detected on visual inspection include distention (such as with abdominal effusion), deformity (caused by a large abdominal mass or hernia), swelling (such as with cellulitis associated with urine leakage), and bruising (associated with coagulopathy or blunt trauma). Bluish-red discoloration around the umbilicus (Cullen's sign) is indicative of intraabdominal hemorrhage. Visual inspection may also reveal puncture wounds (associated with penetrating trauma such as animal bites or projectiles), but the wounds may not be evident without clipping of abdominal hair.

Abdominal auscultation is performed to characterize gut sounds. Increased gut sounds may be evident in acute cases of enteritis, intestinal obstruction, and toxin ingestion. Absence of gut sounds suggests ileus, chronic intestinal obstruction, peritonitis, or abdominal effusion. Anorexia causes decreased intestinal motility, necessitating a long period (2 to 3 minutes) of auscultation before ascertaining that gut sounds are absent. Failure to auscult abnormal (increased or absent) gut sounds does not mean that the abdomen is normal; normal gut motility may be maintained in the early posttraumatic period and in early peritoneal effusion.

Percussion can be performed with or without the aid of a stethoscope to detect hyperresonance (indicating intraabdominal air, usually a gas-filled viscus) or hyporesonance (indicating intraabdominal fluid). If the animal is standing, a fluid line may be percussed between areas of hyperresonance and hyporesonance. Ballottement can be performed in standing and recumbent animals by tapping the abdomen and looking for a ripple effect to confirm the presence of intraabdominal fluid. Animals with a large amount of intraabdominal or extraabdominal fat can appear to ripple on ballottement, yielding a false-positive diagnosis of abdominal effusion.

The abdomen is palpated to detect pain; masses; and enlargement, displacement, or other abnormalities of abdominal organs. Superficial palpation is used to detect, characterize, and potentially localize pain and should be performed before deep palpation. Reproducible abdominal guarding ("splinting") in response to superficial palpation indicates abdominal pain. Stimulation of irritated parietal peritoneum by superficial abdominal palpation is a major reason for the pain response. Another potential response to parietal peritoneum stimulation is nausea and vomiting. Deep palpation should be performed to characterize the structures and abnormal findings in each of three regions: cranial, middle, and caudal abdomen. The final evaluation of the caudal abdomen should include digital examination per rectum to assess the prostate, pelvis, pelvic urethra, sublumbar lymph nodes (if enlarged), and rectum and to evaluate the character and color of the stool.

The physical examination will not necessarily provide a definitive diagnosis, nor will it necessarily dictate a particular therapeutic measure. However, it will help the clinician select the most appropriate diagnostic tests and, if performed serially, will keep the clinician abreast of changes in patient status.

Clinical Pathology

Laboratory testing of blood and urine is useful in providing confirmatory data, sometimes leading to a definitive diagnosis and, probably most important, providing a current picture of the patient's hematologic and metabolic status. A complete blood count provides information regarding anemia, platelet numbers, and hydration status (packed cell volume and total serum solids), which are important influences on treatment decisions. The leukogram provides information regarding the inflammatory status of the condition. A biochemistry

profile may help localize the underlying disease to a specific organ and gives important information about the patient's acid-base balance and electrolyte status. Urinalysis, especially when interpreted in conjunction with biochemistry panels, provides essential information regarding renal function and other urinary tract abnormalities. In emergency situations such as when contemplating emergent celiotomy, waiting for laboratory test results can be detrimental to the patient's well-being. In such circumstances an emergency minimal database should include determinations of packed cell volume, total serum solids, serum creatinine or blood urea nitrogen, serum glucose, serum electrolytes, and urine specific gravity, as well as urine reagent strip test results. The remaining tests can be done later on pretreatment samples.

Diagnostic Imaging

Abdominal radiography, ultrasonography, and contrast studies may provide valuable directions to patient management. Abdominal radiographs should be taken as part of the standard evaluation in most cases of acute abdomen. Notable exceptions include (1) evisceration, (2) penetrating trauma (unless there is need to locate projectiles), (3) postoperative abdomen with peritonitis confirmed on abdominal fluid analysis, and (4) suspected cases of gastric dilation-volvulus in which the patient is in respiratory distress. In the latter example, once the animal is stable and the stomach is decompressed, a right lateral abdominal radiograph may be obtained to confirm the diagnosis. Standing lateral views may be used in cases of abdominal effusion that would otherwise have little abdominal detail. Notable positive radiographic findings in cases of acute abdomen include the presence of fluid (abdominal effusion), gas-distended intestines (obstruction or ileus), free abdominal air (ruptured viscus), masses, organomegaly, foreign bodies, urinary calculi, and signs of pancreatitis (loss of detail in the right cranial quadrant and lateral displacement of a gas-filled descending duodenum).

Abdominal ultrasonography is helpful in defining masses and enlarged organs, especially when abdominal effusion causes loss of radiographic detail. Ultrasonography is particularly helpful in the identification of fluid-filled lesions (such as abscesses) and the characterization of abnormalities of the liver, spleen, prostate, and kidneys. Fine-needle aspiration or needle biopsy of abnormal structures or both can be guided by ultrasonographic examination.

Contrast radiography of the gastrointestinal and urinary systems is sometimes necessary in acute abdomen if survey radiographs fail to define a suspected abnormality. Barium studies can be used to confirm and localize gastrointestinal obstruction. Water-soluble contrast agents should be used when gastrointestinal perforation is suspected. Intravenous urography and urethrocystography are used to confirm and localize discontinuity, obstruction, and other physical abnormalities of the urinary system. When diagnostic imaging fails to clearly define the diagnosis and course of therapy, sampling of abdominal fluid is necessary.

Abdominocentesis and Diagnostic Peritoneal Lavage

Sampling of abdominal fluid is most commonly performed to determine if the patient requires exploratory celiotomy, particularly emergent celiotomy. Abdominocentesis may result in a diagnostic sample if the abdominal fluid is of sufficient volume (approximately 20 ml/kg). Typically each of four abdominal quadrants is aseptically tapped using a hypodermic needle in an open drop technique or by attaching a syringe for gentle aspiration. Alternately a multiholed catheter may be used. A standard over-the-needle intravenous catheter can be modified for abdominocentesis by making side holes with a scalpel blade. Care should be exercised to make the side holes small and smooth to prevent kinking and tearing of the catheter within the abdomen. The four-quadrant tap is performed with the animal in a standing position if it can stand voluntarily. If all four sites fail to yield fluid or are otherwise nondiagnostic, diagnostic peritoneal lavage is the next step.

Diagnostic peritoneal lavage is performed with a multiholed catheter. Commercially available peritoneal lavage catheters can be used, or standard intravenous catheters can be modified as described for abdominocentesis. I prefer to use a commercially available thoracocentesis catheter (Kendall Turkel Safety Thoracocentesis System, Covidien Animal Health and Dental Division, Mansfield, MA) that has a protected needle-stylet and four offset side holes. The ventral midline just caudal to the umbilicus has been recommended for diagnostic peritoneal lavage catheter placement (Crowe, 1988). However, I prefer to enter the abdomen just to the right (2 to 3 cm in midsize dogs) of the umbilicus to avoid interference with the falciform ligament and median ligament of the bladder. The right side is used to minimize the chance of iatrogenic damage to the spleen and descending colon. A subcutaneous bleb of local anesthetic is placed at the proposed entry site, and a tiny stab incision is made in the skin with a No. 11 scalpel blade. The catheter is advanced through the skin stab and into the abdomen. Once the catheter is in the abdomen, a syringe is attached, and gentle aspiration is applied. If a diagnostic sample is obtained, there is no need to progress with the lavage. In the absence of an adequate sample, 22 ml/kg of warmed, sterile isotonic saline is infused into the catheter via an intravenous infusion set with rapid gravity flow or by applying moderate pressure to the bag of saline. After completing the infusion, the patient is rolled gently from side to side, and the abdomen is gently ballotted to disperse the saline, taking care not to dislodge the catheter. Careful, slow aspiration of the catheter with a syringe is performed to collect a 10- to 20-ml sample. Ideally all the infused fluid should be removed, but typically only a small portion is retrievable. The catheter can be retained temporarily for serial evaluation of abdominal fluid in some instances, such as for assessing whether hemoabdomen is ongoing.

Fluid from abdominocentesis or diagnostic peritoneal lavage should be evaluated for color, packed cell volume, white blood cell count, and cytologic features. Occasionally bacterial cultures and chemistry panels

should be performed. Red color suggests hemoabdomen. More definitively, a packed cell volume of diagnostic peritoneal lavage fluid that is 5% or greater indicates significant hemorrhage. Cloudiness suggests peritonitis. An elevated abdominal fluid white blood cell count is diagnostic of peritonitis, but the normally reactive response of the peritoneum to insult (such as surgical manipulation) limits the usefulness of cell counts for determining sepsis (Kirby, 2003). Cytologic characteristics are more meaningful than are cell counts in differentiating septic from nonseptic peritonitis. Toxic changes in neutrophils and the presence of intracellular or extracellular bacteria indicate septic peritonitis. In such cases aerobic and anaerobic bacterial cultures are appropriate, particularly if antibiotic therapy is to be initiated before surgical samples can be obtained. However, intraoperative culture samples are preferred.

In cases of suspected urinary system disruption, the most useful chemistry evaluation for abdominal fluid is creatinine. Urea nitrogen could also be used but is less desirable than creatinine because it is a smaller molecule and rapidly diffuses across the peritoneum and equilibrates with plasma. Diagnostic peritoneal lavage creatinine that is greater (usually two times greater) than serum creatinine indicates uroabdomen. Alternately potassium concentrations can be used to detect uroabdomen. A ratio of abdominal fluid potassium to peripheral blood potassium greater than 1.9:1 indicates uroabdomen (Aumann, Worth, and Drobatz, 1998). Three other chemistry analytes that are occasionally helpful are bilirubin, amylase, and glucose. Bilirubin test reagents can detect intraperitoneal bile, indicating disruption of the biliary system or duodenum. Elevated abdominal fluid amylase compared with serum amylase indicates pancreatitis or intestinal ischemia (Davenport and Martin, 1992). Abdominal fluid glucose can be helpful in differentiating septic from nonseptic peritoneal effusion. An abdominal fluid glucose concentration that is more than 20 mg/dl lower than the blood glucose concentration indicates septic peritonitis (Bonczynski et al., 2003).

Exploratory Celiotomy

When exploratory celiotomy is necessary in acute abdomen, the initial diagnostics should prepare the surgeon to anticipate certain findings. An acute abdomen condition for which surgery is indicated (see Table 12-1) should be on the differential diagnosis list for the patient in question. Exploratory celiotomy should be performed as soon as possible after the need for it is determined. A decision to delay surgery can be justified when the delay will decrease morbidity or the chance of mortality and when it is necessary for additional stabilization that will make the patient a better surgical candidate. Intraoperatively the surgeon should perform a complete systematic exploratory celiotomy to detect and correct all significant abnormalities. Occasionally during emergent celiotomy, life-threatening problems (such as ongoing hemorrhage) will require immediate attention; systematic exploration can be performed later in the procedure. Only rarely should systematic exploration be abandoned altogether (e.g., in patients judged to be at risk of death or severe disability if recovery from anesthesia does not take place soon).

THERAPY

Specific medical and surgical therapeutic measures for animals experiencing acute abdomen are dictated by the clinical status of the patient and the specific cause of the acute abdomen. Each patient should be considered at risk for deterioration; appropriate resuscitative measures are necessary in some cases before a definitive diagnosis can be achieved. Once the definitive cause is ascertained, specific medical or surgical treatments can be used. It is difficult to identify any common therapy for all cases of acute abdomen other than perhaps fluid therapy. However, there is one treatment that should not be overlooked—analgesic therapy.

If one considers that abdominal pain is present at some point in each case of acute abdomen and that definitive therapy is not necessarily going to immediately resolve the pain, analgesics become important. Analgesics should be administered to both medical and surgical patients. Various analgesic regimens are acceptable, but most patients can be managed with either buprenorphine (dogs and cats) if the major source of pain is visceral (such as a distended organ) or morphine (dogs) if the major source of pain is musculoskeletal (such as abdominal wall trauma). Although morphine would likely be effective for visceral pain, potential side effects (nausea, emesis, urine retention, constipation, and greater chance of respiratory depression than buprenorphine) make morphine a less desirable analgesic for most cases of acute abdomen. Buprenorphine can be given as a continuous-rate intravenous infusion (0.04 mg/kg/day) for the first 12 to 36 hours until a switch can be made to an oral opioid (or nonsteroidal antiinflammatory drug if there are no gastrointestinal concerns). When used, morphine can be given as a continuous-rate intravenous infusion (0.1 mg/kg/hour). As an adjunct to opioid analgesia or to minimize the amount of opioids used, lidocaine (20 mcg/kg/min) may be used (dogs only) as a continuous-rate intravenous infusion for the first 12 to 24 hours. When given together for infusion, buprenorphine (or morphine) and lidocaine may be mixed in the same bag of fluids, typically normal saline or the maintenance crystalloid solution being used for fluid therapy. Analgesics should be given as early in the course of treatment as possible. In surgical patients it is preferable to include analgesic administration as part of the preanesthetic medication and repeat administration as necessary before recovery from anesthesia. In nonsurgical patients and patients who undergo lengthy delays before surgery, analgesics are recommended as soon as it is ascertained that the drug effects will not interfere with the diagnostic evaluation. In most cases of acute abdomen, this means as soon as the physical examination is complete. Withholding analgesics for fear of masking important clinical signs should be the exception rather than the rule. Analgesics are not administered immediately to animals presented in shock but should be initiated soon after the shock state is reversed using the same guidelines discussed earlier. The duration of analgesic administration varies with the individual animal but should be at least 24 hours in both postoperative and nonsurgical patients.

CHAPTER 13

Drainage Techniques for the Septic Abdomen

ADRIENNE BENTLEY, *Philadelphia, Pennsylvania*

DAVID E. HOLT, *Philadelphia, Pennsylvania*

"There is probably no detail in modern surgical pathology that deserves more thorough comprehension, but which is less definitively understood.... than the nature of the reaction of the peritoneum to drainage." John L. Yates, 1905

Since Yates's classic paper, there has been substantial investigation into the indications for and best methods of peritoneal drainage. However, universal guidelines for techniques of peritoneal drainage and consistent indications for their application have not emerged. Prophylactic drainage following routine, uncontaminated intraabdominal procedures has been largely abandoned in human surgery. In veterinary medicine, postoperative abdominal drainage is now generally reserved for cases with generalized septic peritonitis.

Septic peritonitis is a severe, life-threatening condition that poses many challenges for the small animal veterinarian. Obtaining an accurate and timely diagnosis; understanding peritoneal fluid and protein loss, hypovolemia, and the systemic inflammatory response syndrome/sepsis; and effective resuscitation are vital to successful treatment of peritonitis. Control of the source of peritoneal contamination remains the primary goal of exploratory laparotomy in cases of generalized septic peritonitis. More recently the benefits of copious intraoperative peritoneal lavage and the need for postoperative peritoneal drainage have been questioned. Although a detailed discussion of peritoneal lavage is beyond the scope of this chapter,

current recommendations include the judicious use of lavage to remove gross contamination and aspiration of the lavage fluid from the peritoneal cavity before closure (Platell, Papadimitriou, and Hall, 2000). This chapter focuses on the indications for and use of various drainage techniques in septic peritonitis.

Effective drainage of the peritoneal cavity in generalized septic peritonitis requires an understanding of intraperitoneal fluid circulation, normal intraperitoneal pressures, and the response of the peritoneal cavity to insertion of a foreign body such as a drain. Fluid injected into the peritoneal cavity disperses throughout the cavity within 15 minutes to 2 hours, depending on the site of injection (Hosgood et al., 1989). The clinical implication is that although fibrin, the omentum, the viscera, and the mesentery may try to localize a focus of contamination, it is likely that contaminated fluid can spread rapidly throughout the peritoneal cavity. Within the peritoneal cavity the gastrointestinal tract has a luminal pressure exceeding atmospheric pressure, whereas the pressure within the peritoneal space is subatmospheric. Even with experimental insufflation of air, the intraperitoneal pressure never exceeds atmospheric pressure (Gold, 1956). Unless either the intraperitoneal pressure becomes higher than atmospheric pressure or air can enter the peritoneal cavity after surgery through a vent, drainage from the peritoneal cavity will not occur without the use of a vacuum system.

Drains inserted into the peritoneal cavity are rapidly encased by the omentum and viscera (Yates, 1905). Thus in some studies it is not clear if drainage occurs from the peritoneal cavity or, more likely, from the encased area around the drain. In a previous experimental study in dogs, sump-Penrose drains were found to be encapsulated and isolated from the peritoneal cavity at necropsy after 48 hours (Hosgood et al., 1989). Despite this isolation, the drains continued to remove radiopaque contrast material from the peritoneal cavity. The use of closed-suction silicone drains for septic peritonitis has been reported (Mueller, Ludwig, and Barton, 2001). Drains in the cases described continued to accumulate fluid for up to 8 days, seeming to indicate adequate function. However, it is not clear if closed-suction drains are encased to the same extent as sump-Penrose drains and are draining a localized area, or if they retain functional drainage of the peritoneal cavity despite being encased.

INDICATIONS FOR POSTOPERATIVE DRAINAGE

The anticipation of significant postoperative fluid production caused by inability to control the source of contamination, generalized peritonitis, or severe local peritonitis is an indication for postoperative drainage. The efficacy of the peritoneal defense mechanisms may be limited by a large volume of fluid, either ongoing effusion or residual lavage. Phagocytosis of bacteria within fluid depends on the presence of opsonins in the fluid, which can become depleted. Therefore the presence of fluid may allow rapid bacterial proliferation. A large volume of fluid may also limit the localization of the contamination and speed the systemic absorption of bacteria and endotoxins (Platell, Papadimitriou, and Hall, 2000). A large volume of effusion also increases intraabdominal pressure. In some cases intraabdominal hypertension is sufficient to cause cardiopulmonary dysfunction, anuria or oliguria, and intestinal ischemia (abdominal compartment syndrome) (Drellich, 2000; Conzemius et al., 1995).

LOCAL PERITONITIS

In some cases peritonitis may not be generalized at the time of exploratory surgery. The two most common examples of localized peritonitis in small animal surgery are prostatic and pancreatic abscesses. Local peritoneal drainage has been used to treat these conditions and generally involved placement of one or more Penrose drains in the abscess cavity once débridement and local lavage were completed. These techniques have largely been replaced by omentalization. The abscess cavity is located by palpation, intraoperative ultrasound, or aspiration. It is opened, drained, and gently débrided with a moistened gauze sponge. After thorough local lavage with a warm, balanced electrolyte solution, the omentum is packed loosely into the cavity, and the abdominal incision is closed. The immunologic and angiogenic properties of the omentum promote local infection control and healing. The technique has been associated with long-term

success in 19 of 20 dogs with prostatic abscesses (White and Williams, 1995) and 6 of 12 dogs with pancreatic abscesses (Johnson and Mann, 2006).

GENERALIZED PERITONITIS

Primary Abdominal Closure Without Drainage

The decision to close the peritoneal cavity without drainage is based on control of the source of contamination and adequate decontamination of the peritoneal cavity. The clinician then relies on the body's peritoneal drainage and immune defense systems. Fluid absorption occurs primarily by passing through gaps (stomata) in the mesothelial cells into lymphatics and thereby the circulation. More microvilli are present on the mesothelial cells of the visceral peritoneum than the parietal peritoneum to promote movement of fluid toward the diaphragm for absorption. The number of mesothelial microvilli increases and lymphatics dilate in response to peritoneal inflammation. In addition to mesothelial cells, numerous immune cells are present in the peritoneal membrane and omentum, including macrophages, lymphocytes, and mast cells. The immune cells function in bacterial phagocytosis, antigen presentation, and antibody and cytokine production in cases of peritonitis. Finally, production of plasminogen activator inhibitor 1 by peritoneal mesothelial cells promotes the organization of fibrous adhesions, which facilitate phagocytosis and localize contamination (Yao, Platell, and Hall, 2003).

Lanz and colleagues (2001) reported 54% survival in a cohort of 28 cases of canine septic peritonitis managed with source control, intraoperative lavage, and closure of the peritoneal cavity without a means of additional postoperative drainage. As discussed, this method of surgical management relies on peritoneal drainage and may be appropriate when the source of contamination can be controlled definitively and peritonitis is not severe.

Open Peritoneal Drainage

Historically open peritoneal drainage has been reserved for the most severe cases of generalized septic peritonitis, which are anecdotally associated with a large volume of effusion after surgery. Assessment of the severity of peritonitis is largely subjective and based on individual experience but may include evaluation of factors shown in Box 13-1. Clear indications for open peritoneal drainage include the need for relaparotomy and anaerobic infection. Relaparotomy may be necessary in cases of ineffective source control or when additional débridement is required. Although the type of infection may not be definitively known at the time of initial laparotomy, an anaerobic infection may be suspected when the colon is the source of contamination. Although intraabdominal pressure is not routinely measured in the clinical setting, open peritoneal drainage is indicated when intraabdominal hypertension results in clinical signs such as anuria or oliguria (Conzemius et al., 1995).

Open peritoneal drainage is established through a long abdominal incision, extending from the xiphoid

Box 13-1

Factors Evaluated In Determining the Severity of Peritonitis

- Volume of effusion
- Character of effusion: opacity, color, odor
- Presence of gross contamination: fecal matter, food, hair
- Serosal changes of abdominal organs: erythema, encasement with fibrous adhesions
- Distribution of contamination and peritonitis: localized or generalized

process to the pubis and including the most dependent portion of the abdomen. The falciform fat should be excised according to standard exploratory laparotomy technique, but omentectomy is not necessary. The linea alba is closed with nonabsorbable suture in a simple continuous pattern with a gap of 1 to 6 cm between the edges, depending on the patient's size (Fig. 13-1). The subcutaneous tissues and skin are not closed. A sterile bandage consisting of laparotomy sponges and surgery towels underneath routine bandage material is applied and changed at least daily. If the bandage becomes wet from peritoneal effusion or urine or if it becomes displaced, it should be replaced as soon as possible. A urinary catheter helps to maintain the integrity of the bandage, especially in male dogs. Although early reports (Woolfson and Dulisch, 1986; Greenfield and Walshaw, 1987) describe performing bandage changes outside of the operating room with the patient standing, current recommendations include changing the bandage in the operating room with the patient sedated or anesthetized. During each bandage change, adhesions at the incision

Fig. 13-1 Open peritoneal drainage is established by leaving a gap between the edges of the linea alba.

are digitally disrupted; the incision is checked for organ evisceration; and additional surgical procedures such as peritoneal lavage, débridement, and feeding tube placement are performed as needed. The decision to close the peritoneal cavity is based on reassessment of the same factors used in selecting open peritoneal drainage. Clinical studies report a mean duration of open peritoneal drainage of 4 to 5 days, with a range of less than 1 day to as long as 2 weeks (Woolfson and Dulisch, 1986; Greenfield and Walshaw, 1987; Winkler and Greenfield, 2000).

Open peritoneal drainage is regarded as an efficient means of drainage, although evidence supporting this claim is limited. In an experimental study of five normal dogs, open peritoneal drainage resulted in rapid, equal, and relatively complete drainage of radiopaque contrast from the peritoneal cavity. Drainage occurred despite the fact that the laparotomy incisions were partially occluded by omentum in all five dogs at necropsy (48 hours after open drainage was established) (Hosgood et al., 1989). In another experimental study of six normal dogs, extreme variability in the volume of injected saline recovered through open peritoneal drainage precluded conclusions regarding drainage efficiency. Drainage occurred in these dogs despite omental adhesions along the entire length of the laparotomy incisions at necropsy (96 hours after open drainage was established) (Hosgood, Salisbury, and De Nicola, 1991). Similar to omental encasement of drains, the effect of omental adhesions to the laparotomy incision on the volume and distribution of fluid drained is unclear. Experimental studies evaluating the efficiency of open peritoneal drainage are limited by the lack of peritonitis, small number of dogs, and small volume of peritoneal fluid (Hosgood et al., 1989 and Hosgood, Salisbury, and DeNicola, 1991). The presence of peritonitis may help maintain the patency of laparotomy incisions and drains by resulting in a larger volume of effusion and omental adhesions to areas of the peritoneal cavity other than the incision or drain (Hosgood, Salisbury, and DeNicola, 1991). Finally, the minimum efficiency of peritoneal drainage necessary in clinical cases of peritonitis is unknown and likely case dependent.

Hypoproteinemia and nosocomial infection are reported complications of open peritoneal drainage, the clinical significance of which is not well established. Clinical reports have documented a relatively small number of patients with different bacterial culture results at the time of exploratory laparotomy and peritoneal closure. Moreover, the presence of a different bacterium at the time of closure does not appear to impact survival (Winkler and Greenfield, 2000; Greenfield and Walshaw, 1987; Woolfson and Dulisch, 1986). Hypoproteinemia is likely a consequence of septic peritonitis, regardless of drainage technique. Total protein concentration was not different between animals managed by peritoneal closure and open drainage 48 hours after surgery. Although a similar number of animals in each group received hetastarch, more animals in the open-drainage group received blood, plasma, and a jejunostomy tube. Animals in the open-drainage group also stayed in the intensive care unit longer than animals in the closed-peritoneal group (Staat, Monnet, and Seim, 2002).

Vacuum-Assisted Closure

Originally designed for use in a variety of chronic wounds, the use of the vacuum-assisted closure (VAC) device in human medicine has simplified the management of patients with open peritoneal drainage. The VAC device (Kinetic Concepts, Inc., San Antonio, TX) consists of a polyurethane ether foam sponge that is cut to fit the wound. An adherent layer is placed over the sponge, and fenestrated evacuation tubing is placed under the adherent layer and connected to a vacuum pump through a drainage canister (Fig. 13-2). Intermittent subatmospheric pressure is applied to the wound through the VAC device (Venturi et al., 2005). Application of the VAC device to the open peritoneal cavity necessitates the addition of a fenestrated nonadherent layer (polyethylene) between the sponge and the peritoneal contents. The device is changed in the operating room as needed (Scott, Feanny, and Hirshberg, 2005). Use of the VAC device promotes wound healing by increasing blood flow, decreasing tissue edema, and removing excess fluid. As a result, bacterial counts are also decreased in the wound (Venturi et al., 2005). The VAC device may provide advantages over traditional open peritoneal drainage in veterinary patients by allowing the volume of effusion to be quantified and decreasing the frequency of labor-intensive bandage changes.

Closed-Suction Drainage

Closed-suction drainage is likely the most commonly used technique for the management of septic peritonitis in veterinary patients. Commercially available closed-suction drains consist of a fenestrated silicone drain connected to an external reservoir by a nonfenestrated tube such as the Jackson-Pratt drain (Cardinal Health [Fig. 13-3]). The drain is typically positioned near the diaphragm and liver in the most dependent portion of the peritoneal cavity, although a more caudal position may be appropriate, depending on the source of the contamination. The nonfenestrated portion of the drain is exited through a small paramedian incision in the body wall and secured with a purse string and

Fig. 13-2 Components of a closed-suction drain include a bulb reservoir connected to the fenestrated intraabdominal portion of the drain. (Jackson-Pratt drain courtesy Cardinal Health.)

Fig. 13-3 Components of the vacuum-assisted closure (VAC) device include a foam sponge, fenestrated evacuation tubing, and an adherent layer. (Courtesy Kinetic Concepts, Inc.)

finger trap of nonabsorbable suture. Compression of the bulb reservoir creates negative pressure within the peritoneal cavity. A bandage is typically applied to cover the exit site of the drain and to provide a means of attaching the bulb reservoir to the patient. The contents of the reservoir are easily emptied, typically every 6 hours.

Mueller, Ludwig, and Barton (2001) reported 70% survival in a cohort of 30 dogs and 10 cats with septic peritonitis managed with closed-suction drains. Drains were in place for a mean of 3.6 days with a range of 2 to 8 days. The volume of fluid produced was variable but decreased with time. The drains remained patent until removal as evidenced by ongoing fluid collection. However, it is unclear if the closed-suction drains removed fluid from the entire peritoneal cavity and what percentage of the total peritoneal fluid volume they drained. No significant complications were reported with use of the closed-suction drains. Only five patients had bacterial cultures of peritoneal fluid performed both at the time of surgery and drain removal. In the two patients with a positive culture at drain removal, different bacteria were isolated compared to the intraoperative cultures, and both patients survived.

Closed-suction drains are relatively inexpensive and easy to place and seem to be free of significant complications. Advantages of closed-suction drainage over open peritoneal drainage include the ability to quantify the volume of effusion and decreased cost and labor. Closed-suction drains have an advantage over physiologic peritoneal drainage in their apparent ability to drain a large volume of effusion rapidly. In addition, closed-suction drains provide readily available peritoneal fluid samples after surgery for cytologic and biochemical analysis. Their use is indicated in most cases of septic peritonitis when the need for postoperative drainage is anticipated but the severity of the peritonitis or volume of effusion does not warrant open peritoneal drainage.

Summary

Postoperative drainage is indicated in septic peritonitis because a large volume of effusion has detrimental effects

Table 13-1

Comparison of Common Peritoneal Drainage Techniques

	Closure Without Additional Drainage	Open Peritoneal Drainage	Closed-Suction Drainage
Efficiency/efficacy	Relies on host peritoneal mechanisms	Uncertain	Uncertain
Labor/nursing care	Minimal	Extensive	Moderate
Cost	Minimal	Expensive	Moderate
Other		Allows relaparotomy	Volume of effusion quantified

Table 13-2

Suggested Criteria for Selecting a Method of Peritoneal Drainage

Peritoneal closure without additional drainage	Definitive control of the source of contamination Minimal peritonitis
Open peritoneal drainage	Inability to control the source at first laparotomy Need for additional débridement at second laparotomy Suspected anaerobic infection such as colonic source Severe peritonitis Abdominal compartment syndrome
Closed-suction drainage	Definitive control of the source of contamination Moderate peritonitis

on peritoneal defense mechanisms and organ function. Table 13-1 shows a comparison of the most commonly used peritoneal drainage techniques, including closure of the peritoneal cavity without additional drainage, open peritoneal drainage, and closed-suction drainage. Patient factors to consider in selecting a method of peritoneal drainage include the success of source control and the severity of the peritonitis (Table 13-2). Cost and the availability of intensive nursing care may also influence the technique selected.

Gastric Dilation-Volvulus

KAROL A. MATHEWS, *Ontario, Canada*

Gastric dilation-volvulus (GDV) is a complex medical and surgical emergency. Potentially it can occur in any size or breed of dog, as well as in cats, but typically it is problematic in large and giant breeds of dogs. In smaller breeds the dachshund is overrepresented. Deep-chested conformation may increase the susceptibility to GDV. The prevalence of GDV increases with increasing age, with the greatest occurrence between 7 and 10 years of age. The frequency of occurrence has been reported at 2.4 to 7.6 per 1000 canine hospital admissions (Glickman et al., 1994). The cause of GDV has not been fully elucidated. Delayed gastric emptying, pyloric obstruction, aerophagia, and engorgement contribute to gastric dilation (GD), with volvulus possibly occurring secondarily. Gastric volvulus can occur without prior dilation. Exercise after consuming a large meal may predispose to GDV. Splenic torsion has also been causally implicated because malposition of the spleen frequently occurs with GDV; however, GDV can occur in splenectomized dogs. Inhibition of gastric motility by pharmacologic agents, blunt abdominal trauma, spinal cord injuries, prolonged surgical procedures, or prolonged recumbency can predispose dogs to GD. Cereal diets have been suggested as a cause for GD; however, studies have not been able to confirm this finding. Recently a study specifically investigating the potential risk of GDV in predisposed dogs consuming dry dog foods with an increasing number of plant protein ingredients such as soy, wheat, corn and rice among the first four label ingredients determined that there was a 2.4-fold increased risk of GDV when an oil or fat ingredient was among the first four ingredients (Raghavan, Glickman, and Glickman, 2006). This discussion focuses on the initial and postoperative treatment of the animal with GDV. A detailed description of the pathophysiology of GD and GDV is covered elsewhere (Leib, 1987) and is only briefly outlined here as a basis for treatment rationale. The various techniques used for surgical correction of GDV can be obtained from standard surgical texts.

As a consequence of GDV, local and systemic effects occur to varying degrees. Gastric ischemia results in gastritis progressing to necrosis, with possible perforation and peritonitis. Compression of the caudal vena cava and portal vein results in decreased venous return to the heart, with subsequent reduction in cardiac output and systemic arterial blood pressure and perfusion of the myocardium and gastrointestinal tract. With gastrointestinal mucosal injury and subsequent translocation of bacteria and endotoxins, the patient is predisposed to sepsis and septic shock. Avulsion of the short gastric and right gastroepiploic vessels may occur, causing intraabdominal hemorrhage. The splenic veins may also become

thrombosed. The effects of these events are hypotension, hypovolemia (blood loss, plasma loss, increased production and sequestration of gastric secretions), hypoxemia, acid-base and electrolyte abnormalities, sepsis, myocardial dysfunction, and disseminated intravascular coagulation (DIC). Prognosis for recovery may be associated with severity of systemic effects. Plasma/blood lactate measurements greater than 6 mmol/L have been associated with a 39% incidence of gastric necrosis (De Papp, Drobatz, and Hughes, 1999). Twenty-eight percent to 38% postoperative mortality has been associated with gastric resection, and 32% to 38% with the requirement for splenectomy. Although this information may be an indicator of prognosis, caution is required when imparting this information to clients since most dogs recover with optimal preoperative and postoperative management.

PRESENTATION

The clinical signs vary with the extent of GD or GDV and may not parallel the degree of gastric or splenic injury. Owners aware of the clinical signs associated with GDV may seek veterinary assistance at the onset of GD, whereas dogs left alone for several hours may present moribund. Typically dogs with GD or GDV have varying degrees of distention of the cranial abdomen with hypersalivation and unproductive retching. These animals are restless, dyspneic, or tachypneic and may or may not be depressed or moribund. In the early stages of GD, physical examination may reveal increased heart rate with strong pulses, normal capillary refill time, and mucous membrane color. In animals with advanced GDV, weak, rapid pulses—possibly associated with pulse deficits—are present; mucous membranes may be pale pink to pale gray with prolonged capillary refill time and the presence of petechiae, and the cranial abdomen may be tympanic with splenomegaly or free abdominal fluid present.

DIAGNOSIS

The diagnosis of GDV is often obvious from the presenting clinical signs. Radiographic examination is necessary and useful if the diagnosis is equivocal or, if after decompression, surgical management may not be an option (differentiation of dilation from volvulus will direct further management). The ability to pass an orogastric tube does not rule out the presence of volvulus.

When necessary, abdominal radiographs with the dog in right lateral recumbency are usually diagnostic. Evaluation of this radiographic view initially may minimize

the patient stress associated with obtaining multiple radiographic views. When volvulus is present, the pylorus is visualized on a right lateral survey radiograph as a gas-filled structure dorsal and cranial to the gastric fundus. A compartmentalization line is frequently observed between the pylorus and fundus. This line represents the pyloric antral wall folding back and contacting the fundic wall. The pylorus cannot be clearly identified in a left lateral projection. Free air within the abdomen may indicate gastric rupture or air leakage after gastrocentesis.

Electrocardiographic monitoring is essential in the patient with GDV and evidence of cardiac arrhythmias. Ventricular arrhythmias are the most common (Muir, 1982). In addition, sinus tachycardia is almost always present in animals presenting with GDV.

The minimal database required for assessing the patient and diagnosing complications associated with the GDV syndrome includes evaluation of systemic arterial blood pressure; packed cell volume (PCV), total plasma solids (TS), activated clotting time (ACT) or activated partial thromboplastin time (aPTT), platelet count, white blood cell count and differential; blood urea nitrogen and glucose concentrations; venous blood gases or total serum carbon dioxide (these patients are frequently alkalemic in the early stage of GD but eventually become acidemic as the disease advances); and serum electrolytes, including lactate. This information is essential to manage the patient adequately and optimize outcome. A complete serum biochemical profile and complete hemostatic profile should be submitted to detect other potential organ dysfunction when appropriate and affordable.

INITIAL TREATMENT

Initial treatment should be considered in light of the presenting clinical signs and the consequences of the known pathophysiologic events. The primary objectives are to (1) prevent or reverse circulatory collapse (fluid and colloid resuscitation), (2) prevent or reduce the local and systemic events associated with GD or GDV by removing the inciting cause (gastric decompression and lavage), (3) treat associated complications (electrolyte and acid-base abnormalities, pain, cardiac arrhythmias, sepsis), and (4) prepare the animal for surgical treatment. For the rare patient that presents with dilation alone without evidence of circulatory compromise, orogastric decompression is the initial treatment. For the typical patient with GDV, circulatory compromise or collapse is present, and reversal of the shock state should be addressed before gastric decompression. In seriously compromised patients it may be necessary to partially decompress the stomach immediately to avoid impending respiratory or circulatory arrest. Gastrocentesis (see section on gastric decompression) is recommended in these situations to avoid the stress of orogastric intubation. In these patients complete decompression should be avoided until rapid fluid resuscitation is well under way. All patients with GDV require surgical correction as soon as possible because medical management alone results in a 75% recurrence rate.

Circulatory Resuscitation

A 14- or 16-gauge 2- to 4-inch catheter is placed into the jugular or cephalic vein or veins—not the saphenous vein. An alkalinizing (lactate or acetate) isotonic, balanced electrolyte solution (or acidifying if alkalemic (e.g., 0.9%) NaCl solution is administered at 90 to 120 ml/kg/hour initially, with continual monitoring and subsequent adjustment to effect. The crystalloid volume can be reduced by up to 40% if pentastarch (Pentaspán, DuPont Pharma, Canada), hetastarch (Hespan, DuPont Pharma United States) or dextran 70 (Gentran, Baxter) is administered at 10 to 20 ml/kg over 15 to 30 minutes (see Chapter 11). If shock is severe, 4 ml/kg of 5% or 7.5% hypertonic saline is administered over 5 to 10 minutes, followed by the aforementioned infusions of isotonic crystalloid or synthetic colloid solution until clinical signs of shock are reversed (Table 14-1). TS and PCV should be measured every 30 minutes. If the PCV decreases to less than 25% or the TS decrease to less than 45 g/L, whole blood, packed red blood cell, or plasma transfusion should be considered. Blood or plasma is administered at a rate of 20 ml/kg over 1 to 2 hours, depending on the resuscitative needs of the patient. Hemoglobin-based oxygen-carrying products (Oxyglobin) have been reported to improve cardiovascular parameters.

If hypotension persists, one should consider intravenous continuous-rate infusions (CRIs) of dopamine (Intropin, DuPont Pharma) or dobutamine (Dobutrex, Eli Lilly) at 2 to 20 mcg/kg per minute. Adjustment in administration rates should be made as needed to achieve a satisfactory hemodynamic end point (see Table 14-1). Norepinephrine (Levophed, Sanofi Winthrop), 0.05 to 0.3 mcg/kg/minute intravenously (IV), or higher doses to effect, can be administered if dopamine or dobutamine infusions fail to achieve the desired effect.

The most common acid-base abnormality in animals with GDV is nonrespiratory (metabolic) acidosis. This abnormality is frequently corrected by treating the underlying cause (shock) with aggressive resuscitative fluid therapy and gastric decompression. Bicarbonate (HCO_3^-) administration is not routinely necessary but may be

Table 14-1

Parameters to Assess and Goals to Achieve With Fluid and Colloid Resuscitation

Parameter	Goal
Mean arterial pressure	70-80 mm Hg
Systolic blood pressure	100-120 mm Hg
Central venous pressure	3-5 cm H ₂ O
Mucous membrane color	Pink
Capillary refill time	1-2 sec
Heart rate	120-140 beats/min
Peripheral pulse (dorsal pedal) pressure	Moderate to normal strength
Mentation	Improved to normal for the situation
Urine output	1-2 ml/kg/hr

indicated if serum $[\text{HCO}_3^-]$ or total carbon dioxide is less than 12 mEq/L after fluid resuscitation. A suggested dose for HCO_3^- administration (in milliequivalents) can be calculated using the following formula:

$$\text{Body weight (kg)} \times (12 - \text{patient } [\text{HCO}_3^-]) \times 0.3$$

The calculated dose can be administered intravenously over 30 to 60 minutes. Occasionally a patient may have a normal or increased blood pH, and empiric therapy with HCO_3^- may be deleterious. When lacticemia is present, this rapidly resolves with fluid therapy and correction of the dilation-volvulus. In most instances reperfusion restores the acid-base status to normal without treatment with sodium bicarbonate therapy.

Ventricular arrhythmias frequently improve after circulatory resuscitation and gastric decompression; however, treatment is advised by some if the arrhythmia is sustained, paroxysmal, or polymorphic at an instantaneous rate greater than or equal to 170 beats/min (120 beats/min under general anesthesia), greater than or equal to 140 beats/min with mean arterial pressure (MAP) less than 70 mm Hg, when preexisting cardiac disease is present, or when an R-on-T phenomenon or torsades de pointes is observed on the electrocardiogram (see Chapter 162). Initial treatment for ventricular tachyarrhythmias is lidocaine (Xylocaine, Astra) administration at 2 mg/kg intravenously. If the initial bolus is ineffective, one or two additional boluses can be administered within 5 to 10 minutes of the initial bolus. If the arrhythmia is lidocaine-responsive, a CRI of lidocaine at 30 to 80 mcg/kg/minute is established. Failure of the rhythm to improve with lidocaine administration (reduction in rate to 120 to 140 beats/min and a reduction in abnormal complex morphologic features) requires reassessment of the electrocardiographic diagnosis and overall status of the patient (e.g., electrolyte, acid-base, sepsis, and pain) with consideration of alternative antiarrhythmic therapy. One should not expect to totally abolish the arrhythmia and should not feel compelled to treat the ventricular rhythms that are neither very fast nor causing hypotension. If there is uncertainty as to whether the arrhythmia is ventricular or supraventricular in origin or if the ventricular arrhythmia is not lidocaine responsive, procainamide (Pronestyl, Squibb) is administered intravenously at 6 to 10 mg/kg (rarely up to 20 mg/kg) by 2 mg/kg-increments every 5 minutes (to avoid hypotension). If procainamide administration is effective, it is continued at 6 to 10 mg/kg intramuscularly every 6 hours or as an intravenous CRI of 25 to 40 mcg/kg/minute. The administration of 20% magnesium sulfate solution at 0.15 to 0.3 mEq/kg (12.5 to 35 mg/kg) via 2- to 4-hour intravenous CRI three times in 24 hours may abolish or enhance the treatment response of patients with ventricular arrhythmias. For life-threatening arrhythmia, a magnesium sulfate dose of 0.15 to 0.3 mEq/kg could be administered over 15 to 20 minutes. Caution must be used with magnesium sulfate administration in patients with renal insufficiency (Bonagura, 1995, p. 132). Sinus tachycardia frequently resolves with resuscitative treatment and analgesic support. If sinus tachycardia persists, one should consider hypotension, hypovolemia (i.e., if not hypotensive, the possibility of

maximal patient compensation requiring continuation of resuscitative treatment), hypoxemia, anemia, hypercarbia, inadequate control of pain, gastric perforation, splenic infarction, or other major organ complication that requires immediate exploratory celiotomy.

Potassium-supplemented fluids, delivered through an intravenous line separate from the rapid infusion of crystalloids, should be administered at a dosage of 30 to 80 mEq/L delivered at a maintenance fluid rate when serum potassium concentrations are 3.5 mEq/L to less than 2 mEq/L, respectively. If the animal is acidemic, the serum potassium concentration may decrease during treatment with alkalinizing solutions. This possibility should be anticipated, assessed, and addressed by an increase in the rate of potassium infusion. Potassium infusions can be delivered at a maximal rate of 0.5 to 1 mEq/kg/hour when serum potassium levels are less than 3 mEq/L, ventricular arrhythmias are present, and continuous electrocardiography and serial serum potassium monitoring are possible every 2 hours.

Antibiotics with a spectrum of activity directed against gram-negative and anaerobic bacteria should be administered slowly intravenously during fluid resuscitation (cefoxitin, 20 mg/kg IV q6h, or ampicillin, 20 mg/kg IV q6h). Translocation of gut bacteria into the systemic circulation is a common complication of GDV and gastrointestinal hypoperfusion.

Administration of corticosteroids to patients with GDV is controversial. However, because of the potential for gastric hemorrhage, corticosteroids are not administered to patients with GDV at our hospital. Furthermore, the administration of nonsteroidal antiinflammatory analgesics is not recommended. Deferoxamine (Desferal, Ciba-Geigy Pharmaceutical Inc.), 50 mg/kg slowly intravenously, administered 10 minutes before gastric decompression, has shown promise in prevention of reperfusion injury when administered to dogs with experimentally induced GDV. However, this drug can cause significant hypotension when administered at 50 mg/kg; therefore 20 to 25 mg/kg is suggested, given over 10 minutes to avoid hypotension. Clinical trials are needed to demonstrate its efficacy and limitations.

Gastric Decompression

After resuscitative fluid administration, gastric decompression is initiated. If the animal requires sedation, butorphanol (Torbugesic, Ayerst), 0.2 to 0.4 mg/kg IV, fentanyl 2 to 5 mcg/kg, hydromorphone (Dilaudid, DuPont Pharma), or oxymorphone (Numorphan, DuPont Pharma) 0.02 to 0.05 mg/kg IV, is administered cautiously (to avoid vomiting) to effect. The addition of diazepam (Valium, Roche), 0.2 to 0.5 mg/kg IV, can be used concomitantly if needed in noncompliant dogs before decompression. If surgical correction is planned, hydromorphone or oxymorphone administration is preferred since these drugs reduce the inhalant anesthetic requirements, have greater analgesic effect, and produce a better sedative effect that facilitates tracheal intubation.

To perform orogastric decompression, the dog is placed in sternal or lateral recumbency or in an upright sitting position. A large-bore tube is premeasured from the chin

to the xiphoid, and the distance is marked on the tube with tape. The tube is lubricated with water-soluble jelly and passed carefully through an oral speculum (or 2-inch roll of tape) through the esophagus and into the stomach (the mark on the tube is at the level of the incisor teeth). Rupture of compromised areas of the lower esophagus or stomach can occur if excessive force is used in orogastric intubation. If resistance to passage of the orogastric tube is experienced, the tube should be rotated gently while reattempting passage, or the position of the dog changed to facilitate passage.

Gastrocentesis should be performed immediately in patients with severe gastric distention and incipient cardiopulmonary arrest or in patients in which attempts at orogastric intubation have been unsuccessful and delay in partial decompression with further repositioning will be detrimental to the patient. A 10- × 10-cm area is aseptically prepared caudal to the right costal arch. The area is percussed to identify the tympanic stomach and to avoid needle puncture of the spleen. An 18-gauge needle or needle-styled catheter is placed through the abdominal wall into the lumen of the stomach to allow gas to escape. Further decompression is often not necessary if the patient is to undergo surgical correction immediately. However, if surgical correction may be delayed, orogastric decompression should be repeated after gastrocentesis to reduce the rapid accumulation of gas. Orogastric decompression is more easily performed at this time because release of pressure on the cardia usually facilitates passage of the tube. After orogastric decompression, the stomach is lavaged with warm tap water to remove residual food. The absence of blood or coffee ground material in the lavage fluid does not rule out the presence of gastric necrosis.

If surgical correction cannot be performed immediately, decompression may be maintained by placement of a weighted nasogastric tube with stylet (EN-tube, Entech Inc., Lebanon, NJ), a pharyngostomy tube, or a temporary gastrostomy. Intermittent orogastric intubation is not recommended because this procedure is stressful and iatrogenic gastric rupture is a potential concern with repeated orogastric tube placement. The indications for maintaining temporary gastric decompression in these patients include (1) maintenance of gastric decompression for patient transportation to a referral facility, and (2) unavailability of a surgeon to perform immediate surgical intervention. Preparation for the placement of a temporary gastrostomy is as described for gastrocentesis but should only be considered when definitive correction is not possible for several hours. Anesthesia of the area to be incised can be obtained by infiltration of 4 to 6 ml of 1% lidocaine through the skin and subcutaneous and muscle layers, including the peritoneum, in an inverted L pattern. A 6-cm incision is made through the skin, and the approach to the peritoneum is made through muscle separation. The peritoneum is incised with caution since the stomach is adjacent to it. A circumferential, simple, continuous suture pattern is placed through the skin, abdominal wall, serosa, and muscles of the stomach. The stomach is then incised. Gastric emptying and lavage are then performed. Any temporary gastrostomy is closed and locally irrigated during the subsequent surgical approach

for definitive surgical correction. In general, the recommendation would be for definitive surgical correction for GDV within 1 to 2 hours after presentation in the majority of cases. Early intervention, after an initial period of circulatory resuscitation, has been shown to reduce postoperative fatality rates (Brockman, Washabau, and Drobatz, 1995). The disadvantages of postponing surgical intervention are (1) the increased prevalence of cardiac arrhythmias by 12 to 72 hours, (2) an increased risk of splenic and gastric infarction resulting from continuing malposition, and (3) the increasing risk with time of gastric perforation with consequent peritonitis (Bonagura, 2000).

SURGICAL TREATMENT

Preinduction oxygenation is recommended. Before inducing general anesthesia, lidocaine, 2 mg/kg IV, should be administered, followed with an infusion of 50 to 120 mcg/kg/minute (dose is dependent on presence or absence of ventricular arrhythmias) to reduce isoflurane requirements (Valverde). Anesthesia regimens to be considered in patients with GDV include hydromorphone, 0.02 to 0.05 mg/kg, or fentanyl, 5 to 10 mcg/kg, and mask administration of isoflurane (Forane, Ohmeda) for the severely compromised patient; and ketamine (Ketaset, Ayerst), 2 to 5 mg/kg, combined with diazepam, 0.1 to 0.3 mg/kg, and isoflurane for the stable but moderately depressed patient. Consider a fentanyl infusion of 5 to 20 mcg/kg/hour to reduce the inhalant further. Crystalloid, colloid, blood, or blood component administration; antiarrhythmic and electrolyte therapy; and continuous electrocardiography, along with serial blood pressure monitoring, should continue throughout the intraoperative period.

When early presentation is with dilation alone and no involvement of other organs or metabolic abnormality of importance, the laparoscopic gastropexy may be an alternative to laparotomy (Rawlings et al., 2002). The permanent incisional gastropexy technique is fast and not technically challenging; it is now the preferred technique for definitive correction of GDV in our hospital because of ease of performance and efficacy and has replaced the previously used belt loop gastropexy technique. The tube gastropexy was the preferred technique described in one report (Brockman, Washabau, and Drobatz, 1995). Regardless of the gastropexy used, during definitive surgical correction it is recommended that areas of gastric necrosis or questionably viable stomach be removed. Invagination into the gastric lumen of nonviable or potentially nonviable tissue, as suggested in some texts, can potentially predispose to postoperative DIC. Similarly, if there are questionable areas of necrosis in the spleen or if the spleen does not return to a normal size after derotation (performed before gastropexy to allow time for venous drainage), it should be removed. Unless pyloric outflow obstruction can be clearly demonstrated, pyloroplasty is not necessary, and the extended surgical time required to perform this procedure may contribute to patient morbidity. If there is a concern about pancreatitis or if any extended (>24 hours) restriction of oral food intake is anticipated, a jejunostomy tube should be placed for nutritional support.

POSTOPERATIVE MANAGEMENT

Recent studies in patients with GDV and surgical intervention reported mortality rates as low as 15% (Brockman, Washabau, and Drobatz, 1995) to 18% (Brouman et al., 1996). Of the nonsurvivors, postoperative mortality associated with gastric resection was 28% (Brockman, Washabau, and Drobatz, 1995) to 35% (Brouman et al., 1996); with splenectomy, it was 32% (Brouman et al., 1996) to 38% (Brockman, Washabau, and Drobatz, 1995); and with cardiac arrhythmias that were present on admission, postoperative mortality was 38% (Brouman et al., 1996). Cardiac arrhythmias developing *after surgery* did not influence outcome (Brouman et al., 1996; Brockman, Washabau, and Drobatz, 1995). With current standards of critical care management in the patients, survival rates appear to be higher than those reported.

Complications to be anticipated in patients after surgical correction of GDV include cardiac arrhythmias; fluid overload; gastroparesis and ileus; vomiting; pancreatitis; DIC; gastric and incisional dehiscence; gastric ulceration; ischemic necrosis of stomach, spleen, or gallbladder with peritonitis; incarceration of small bowel dorsal to the gastropexy site; or the development of acute renal failure. The intensity of postoperative care will vary, depending on the severity of illness and surgical intervention. To provide optimal care, for the first 24 hours the clinician should (1) continuously or serially observe the electrocardiogram and measure hemodynamics (goals are MAP >70 mm Hg, systolic pressure >110 mm Hg, central venous pressure (CVP) of 3 to 5 cm H₂O), provide pain assessment and treatment (hydromorphone 0.05 to 0.2 mg/kg q4h or to effect), and measure urine output (1 to 2 ml/kg/hour); (2) assess at least every 8 hours serum electrolytes (goals are electrolytes within normal limits, with K⁺ >4.5 mmol/L, lactate <2.5 mmol/L nonrespiratory acid-base status (venous pH 7.28 to 7.4, [HCO₃⁻] 16 to 24 mmol/L, base excess \pm 5), PCV (25 to 45%), and TS (45 to 70 g/L); (3) measure every 12 hours ACT (normal range 70 to 100 seconds) and blood glucose concentration; and (4) assess each day serum magnesium, creatinine, albumin concentrations and complete blood count, and antithrombin levels (when DIC is suspected). Treatment approaches for abnormalities detected on serial postoperative testing need to be individualized to the patient.

The major electrolyte disturbance seen after surgery in almost all postoperative GDV patients is hypokalemia. Hypokalemia potentiates cardiac arrhythmias, and hypokalemia is potentiated by hypomagnesemia. In severely hypokalemic patients potassium supplementation in intravenous fluids may exceed 80 mEq/L even though crystalloids are being delivered at two to three times the normal requirement for maintenance. Magnesium sulfate 20% can be administered by intravenous CRI at 0.25 mEq/kg (30 mg/kg) divided over 4 hours and repeated at 8-hour intervals for 24 hours or as an intravenous CRI of 1 mEq/kg/day (125 mg/kg/day). Magnesium levels must be measured daily at this infusion rate. Serum potassium levels require frequent (q8-12h) monitoring during potassium and magnesium infusions.

Sinus tachycardia should not be present after surgery in patients without primary cardiac disease recovering

from GDV. The presence of sinus tachycardia in these patients does not require antiarrhythmic therapy since this rhythm often represents a physiologic response to heart failure, pain, hypoxia, anemia, hypotension, sepsis, and other potential problems previously mentioned. These primary abnormalities should be identified and treated. However, if a primary supraventricular tachyarrhythmia has been identified, appropriate antiarrhythmic therapy is administered based on the specific rhythm problem (see Chapters 161 and 162). Ventricular tachyarrhythmias are treated as described in the section on initial treatment.

In the postoperative patient with GDV, isotonic crystalloid fluids and synthetic colloids are administered at a rate that maintains normal hydration, acid-base status, and urine output. Synthetic colloids, 20 to 30 ml/kg/day, should be administered when large-volume crystalloids are required to maintain the MAP at greater than 70 mm Hg, systolic arterial blood pressure at greater than 110 mm Hg, and urine output at greater than 1 ml/kg/hour or to prevent the development of interstitial or pulmonary edema in patients with decreased TS or colloidal osmotic pressure.

Antibiotic therapy as recommended in the section on initial treatment should be continued intravenously for 72 hours in patients requiring gastric resection or when gastric mucosal injury is highly suspect. Patients with simple GD or GDV without notable mucosal injury do not require antibiotic therapy after surgery.

It is not uncommon for patients with GDV or GD to acquire gastric atony and ileus after surgery. This occurrence predisposes animals to recurrence of GD and vomiting. If a gastrostomy tube is not in place, maintenance of gastric decompression may require the placement of a nasogastric tube. Metoclopramide administration (Reglan, Wyeth-Ayerst), 0.2 to 0.5 mg/kg every 8 hours subcutaneously or 1 to 2 mg/kg per day by intravenous CRI, is recommended as a promotility drug to enhance gastric emptying and as an antiemetic. To enhance gastric mucosal healing, reduce the possibility of gastric ulceration with hemorrhage, and prevent esophageal stricture secondary to reflux esophagitis, famotidine 0.5 mg/kg q12h IV, and sucralfate (200 mg/ml suspension) (Sulcrate or Carafate, Nordic), 5 ml/dog q8h PO, are recommended. Therapy may range from 2 to 5 days.

Gastric necrosis has been associated with abnormal hemostatic profiles (Millis, Hauptman, and Fulton, 1993). Therefore, when gastric or splenic necrosis is apparent at surgical correction, it should be assumed that DIC is present, especially if associated with prolonged ACT. These patients may benefit from at least one fresh frozen plasma transfusion. Heparin therapy is not routinely recommended; however, if thrombosis is a concern, the current suggestions are 100 to 150 U/kg SC q8h of unfractionated heparin or alternatively, after loading with this dose, a CRI of 12 to 15 U/kg/hour, although a dosing regimen is not established. The CRI 12 U/kg/hour via jugular catheter is recommended when jugular catheters are in use. aPTT or ACT should be monitored before each subcutaneous heparin dose or twice daily with the CRI. The goal of heparin therapy is to achieve a PTT or ACT of 1.5 to 2 times normal before the next dose. At our hospital

normal ACT (human axillary incubation) is 75 to 100 seconds, and the target value with heparin therapy is 150 to 180 seconds.

The continued "bedside" assessment of these patients includes serial assessment of ACT, TS, PCV, and platelet count and physical examination (incisional oozing, petechial hemorrhages, and deterioration in attitude). If further abnormalities develop in any of the assessed parameters, another unit of fresh frozen plasma or fresh whole blood (to raise the PCV to 25% to 30%) should be administered, and consideration given to the possibility of an ongoing problem (progression of gastric or splenic necrosis) or another complication such as sepsis that may require further surgical treatment.

In most patients with uncomplicated surgical correction of GDV or GD, water should be offered at 12 hours after surgery, and a low-fat, good-quality protein canned dog food slurry should be offered soon after if the patient is alert and not vomiting. Oral feeding of patients with gastric resection should be started at the discretion of the surgeon based on the extent of, or surgical complications associated with, the resection and the presence or absence of a jejunostomy feeding tube. However, in general, feedings do not differ from noncomplicated cases.

If a jejunostomy feeding tube is in place, a CRI of an electrolyte solution with 5% dextrose (Plasma-Lyte, 56 with 5% dextrose, Baxter) is delivered at 0.5 ml/kg via the tube for the initial 12 hours after surgery. If this is tolerated by the patient, the addition of a prepared liquid diet (Canine Clinicare, PetAg) at one half the daily non-protein caloric requirements (see equation) diluted 50:50 with the aforementioned crystalloid solution is delivered at 0.5 ml/kg/hour for the subsequent 24 hours. If no signs of discomfort or nausea are noted after this 24-hour infusion, the infusion should be increased to meet full nutritional requirements. Peripheral intravenous fluid therapy should be reduced by the appropriate amount once oral intake occurs or enteral nutritional support is instituted. The duration of jejunostomy feeding is individualized to each patient. A goal for daily caloric requirement to achieve over a 1- to 3-day period, depending on extent of gastric injury, is:

$$1.5 \times [70 (\text{body weight in kg}^{0.75})]$$

Parenteral nutritional support is recommended for patients unable to eat, drink, or receive enteral nutrition for more than 36 hours after surgery (see Chapter 36). A common nutritional support technique used in our hospital is the administration of a partial parenteral nutritional (PPN) solution. In 1 L there is a 3.3% concentration of amino acids (Travasol, Baxter) and a 3.3% concentration of dextrose in an electrolyte solution (Plasma-Lyte 56 with 5% dextrose, Baxter). This can be prepared by removing 330 ml of the electrolyte solution from a 1-L bag and replacing it with 330 ml of Travasol under sterile conditions. Lipids (20% Intralipid, Clintec) can be piggy-backed into the administration set and delivered at a volume up to 50% of the patient's nonprotein caloric requirements. Both can be delivered through a peripheral intravenous catheter. Although strict aseptic technique is used in preparing and delivering this solution, a ded-

icated peripheral line offers ease of PPN administration without compromising the patient through administration via a common central venous access that may be used for CVP monitoring, blood sampling, and delivery of crystalloid fluids or medications. The amino acid-glucose solution is delivered as an intravenous CRI at a rate of 1 to 1½ normal daily fluid maintenance requirements. If further glucose supplementation appears necessary, it can be administered with the remaining replacement-maintenance crystalloid fluids. The hourly rate of administration for crystalloid fluid support should be reduced by an amount equal to that delivered via PPN to avoid overhydration.

The length of hospital stay will depend on the severity of illness but is expected to be 2 to 7 days. All dogs that have recovered from GDV or GD should be fed a good-quality canned dog food in small amounts (based on their normal daily nutritional requirements) four or five times daily initially and no less than three times daily in the future to avoid engorgement. Exercise after eating should be avoided. Owners should be made aware that gastropexy is not a guarantee against future episodes of GD or GDV in the patient.

Emergency Management of Open Fractures

ROBERT J. MCCARTHY, *North Grafton, Massachusetts*

Open fractures, defined as those in which fractured bone has been exposed to the external environment, represent between 5% and 10% of all fracture cases seen in small animal practice. Any open fracture must be considered contaminated and a source of potential infection. These fractures require immediate intervention and should be treated as surgical emergencies.

Open fractures have been classified into three types, based on the wounding mechanism and the degree of hard- and soft-tissue damage (Table 15-1). Type I open fractures are the result of the lowest energy trauma and are frequently associated with the sharp point of a fractured bone penetrating the skin from the inside. Wound size is generally less than 1 cm in length. There is little soft-tissue injury, wounds are often relatively clean, and there is no crushing component. The bone end may remain exposed but more commonly returns to lie beneath the skin. Fractures are usually transverse or oblique, with minimal if any comminution. The tibia and radius are common sites of type I open fractures in small animals because of the close proximity of bone to the skin in the antebrachium and crus.

In a type II open fracture an external force produces a penetrating wound that communicates with the fracture from the outside. Wounds are usually greater than 1 cm in length. These fractures have more severe soft-tissue injury and contamination. There is a minimal-to-moderate crushing component to skin and musculature, and fractures may be comminuted. These fractures are about twice as likely to become infected as type I open fractures. Common examples include bite wounds and certain low-velocity gunshot fractures.

Type III open fractures are caused by high-energy trauma from an external source and are characterized by severe soft-tissue damage and contamination. There is often soft tissue or bone loss, and bone may be stripped of soft-tissue attachments. There is generally a severe crushing component. Fractures are usually highly comminuted, and repair may result in cortical defects. Risk of infection is considered about four times that in a type I open fracture. Examples are degloving injuries with underlying fracture and high-velocity gunshot injuries.

INITIAL ASSESSMENT AND EMERGENCY MANAGEMENT

Treatment of an open fracture should be started at home. Owners are instructed to minimize all limb manipulation and to cover the wound and exposed bone with a sterile

dressing if possible. A clean cloth or diaper is an appropriate alternative if bandage materials are not available. Owners should be warned that injured animals may bite, and they should consider placing a muzzle if necessary. Compression is usually sufficient to control hemorrhage during transport to the hospital. Initial veterinary management is directed toward evaluation and treatment of other potentially life-threatening injuries unless the wound is inadequately covered or is hemorrhaging profusely (Box 15-1). In this situation a sterile dressing and pressure wrap should be applied. Ligation of actively bleeding vessels is occasionally required. Bone protruding from the wound should not be reduced into the wound at this time since this allows additional contamination of the fracture site.

Evaluation of the stabilized patient is begun with a thorough case history. Owners are questioned regarding the cause of the injury and the environment in which the injury occurred. It is significant whether the animal was “run into” or “run over” because in the latter situation a significant crushing component is more likely. The environment where the injury occurred may help determine potential wound contaminants and dictate the choice of future antibiotic therapy.

Initial wound evaluation should be directed toward a careful assessment of the neurologic and vascular status of the limb since they may alter treatment options. Simple diagnostic tests include clipping a toenail short to check for active bleeding, evaluation of extremity pulses distal to the wound, limb temperature assessment, and patient recognition of extremity sensation. Although the degree of wound contamination and apparent soft- and bony-tissue trauma should be determined, limb manipulation must be minimized, and wound probing avoided because they increase contamination, cause vascular damage, and result in pain. Potential problems associated with small puncture wounds should not be underestimated because debris may be under the skin, deep in the wound and medullary cavity. Preliminary deep wound cultures should be obtained at the time of initial wound evaluation. In humans 50% to 70% of open fractures produce positive results when cultured at presentation, and in 66% of cases the bacteria cultured at presentation are the same as those isolated later in infected wounds.

After the wound is assessed and cultured, radiographs are obtained, and a more functional immobilization dressing is applied. The purpose of this bandage is to prevent additional contamination, preserve vasculature, and decrease pain. Most organisms that are recovered from the

Table 15-1

Classification of Open Fractures

Classification	Wounding Mechanism	Soft Tissue and Bony Damage	Common Fracture Configuration	Relative Risk of Infection
Type I	Bone fragment protrudes outward from within	Minimal	Transverse, oblique	1
Type II	Penetrating external wound contacts bone	Moderate	Some comminution	2
Type III	Severe external force causes wound	Severe	Severe comminution	4

wound after the development of an orthopedic infection can be traced to the hospital; thus early protection of the wound is critical. Sterile dressings should be used in all cases, and strict asepsis maintained. A splint is generally applied to support open fractures below the elbow or stifle, whereas a spica-type bandage is required to immobilize fractures more proximal on the limb. Fractures proximal to the elbow or stifle are frequently difficult to immobilize properly, and in many cases it may be preferable simply to cover the wound and confine the animal to a small cage.

Antibiotics are always indicated for animals with open fractures because all wounds are contaminated and wounds that occurred longer than 6 to 8 hours before definitive surgical débridement and lavage are infected. In humans antibiotics administered within 3 hours of injury significantly decrease the rate of future wound infection. Risk of infection may be greater in animals with open fractures because of decreased host defense mechanisms caused by stress, or vascular compromise. Choice of antibiotic is based on the cause of injury, nature of the wound, likely bacterial contaminants, and knowledge of commonly isolated bacteria from patients with osteomyelitis. *Staphylococcus* spp. cause between 50% and 60% of bone infections in dogs, and many of these infections are monomicrobial. In general, concerns about penetration of antibiotics into bone interstitial fluid are unfounded.

First-generation cephalosporins such as cefazolin (Kefzol, Lilly, 20 mg/kg q8h) are often the initial drugs of choice because they are broad spectrum, can be given intravenously, are usually effective against β -lactamase-producing *Staphylococcus* spp., and are relatively inexpensive. If contamination with a gram-negative organism is expected, a

fluoroquinolone antibiotic such as enrofloxacin (Baytril, Bayer, 5 mg/kg SQ q24h) or a penicillin-derivative such as imipenem (Primaxin, Merck, 5 to 10 mg/kg IV q6-8h) may be added. Anaerobic infections are more common than previously thought, and clindamycin (Antirobe, Upjohn, 5 to 10 mg/kg PO q12h) or metronidazole (Flagyl, Searle, 25 to 40 mg/kg PO q12h) should be considered in addition to first-generation cephalosporins in animals with severely necrotic, avascular wounds. The initial choice of antibiotic is altered when culture and sensitivity test results become available. In type I and II open fractures that are not infected, antibiotic use can be discontinued immediately after fracture repair. In any type III open fracture or in type I or II open fractures that are infected, more prolonged use is indicated. In general, antibiotic therapy is continued for about 1 month in these cases. Antibiotics can be discontinued at that time if there is no clinical or radiographic evidence of infection.

Recognition of pain is difficult in dogs and cats because even animals with severe pain may show no overt clinical signs. Open fractures are associated with extensive pain and anxiety in humans, and a similar situation is expected in animals. Pain should be treated with narcotic analgesics. In general, pure opioid agonists such as hydromorphone (Dilaudid, Abbott, 0.05 to 0.1 mg/kg IV q6h) or oxymorphone (Numorphan, Dupont, 0.05 to 0.1 mg/kg IV or IM q6h) should be used to treat the severe pain associated with an open fracture (see also Chapter 2). A dermal fentanyl patch may be an adjunct for providing longer-term analgesia.

SURGICAL DÉBRIDEMENT

Patients with open fractures frequently require long hospitalization, multiple surgical procedures, and expensive medications; thus, before initiating definitive wound management and fracture repair, owners should be apprised carefully of the potential prognosis and cost. It is essential that the veterinarian communicate treatment options and prognosis in a manner that allows clients to understand the situation and then make rational, realistic decisions for themselves and their pets. An estimate in writing of the anticipated expense and treatment should be provided. Limb amputation may be a necessary alternative in some cases. Definitive surgical débridement of the open fracture wound should be performed as soon as safely possible, preferably within 6 to 8 hours after injury. This period is considered the “golden period” in which the wound is contaminated but bacteria have not had the opportunity to multiply and spread through adjacent tissues. If the patient is not yet stable for anesthesia, initial débridement can be attempted with a

Box 15-1

Treatment Protocol for Management of Patients With Open Fracture

1. Evaluate patient status and treat life-threatening injuries.
2. Control hemorrhage.
3. Place sterile dressing and bandage during patient stabilization.
4. Assess vascular and neurologic status of limb.
5. Obtain preliminary deep wound culture.
6. Start antibiotic therapy.
7. Manage pain.
8. Obtain radiographs.
9. Perform definitive surgical débridement and fracture fixation within 6-8 hours if possible.

local anesthetic or a regional anesthesia technique such as an epidural. Neuroleptanalgesia can also be considered.

Surgical preparation and removal of gross debris may be performed in the surgical preparation area, but definitive débridement is performed in the operating room. Most orthopedic infections originate from hospital organisms, thus strict aseptic technique is important. Sterile water-soluble gel can be placed in the wound to avoid contamination with hair while clipping. A water-impermeable barrier is placed between the limb and the rest of the body and surgery table during débridement to prevent wicking of contaminated fluids from the environment into the operative field.

The goal of surgical débridement is to convert a contaminated wound to a clean one. All foreign material and contaminated or dead tissue is removed, but undermining wound edges and extensive soft tissue dissection are avoided. Sharp dissection technique is preferred. Dependable features for predicting viability of muscle are ability to bleed, consistency, and contractility. Although commonly used, color is actually a relatively poor criterion because it depends greatly on the available light. If viability is questionable, it is better to leave tissue in place and remove it if necessary during a second procedure. As a guideline for débriding bone, if the bone has no soft-tissue attachment and is not critical for reconstruction of the fracture, it is excised. Bone that has no soft-tissue attachment but is critical for fracture reconstruction should be saved. Any bone that has good soft-tissue attachment is saved in the fracture site.

Wounds are irrigated with liters of isotonic saline or 0.05% chlorhexidine. Tap water has been used for wound irrigation but is not recommended because the hypotonicity of tap water may potentiate cellular damage. There is little evidence for incorporation of antibiotics into lavage fluids in dogs and cats. A pulsating irrigation delivery system is helpful, or lavage can be accomplished with a 35-ml syringe and an 18-gauge needle. Bullets retrieved from gunshot fracture wounds should be saved because of the potential for future litigation. A deep wound culture is obtained at the end rather than the beginning of surgery because this has been shown to correlate better with later infection.

FRACTURE REPAIR

Fracture fixation is performed as soon as safely possible, preferably during the initial wound débridement. If immediate fixation is planned, the operative field, the equipment, and the surgeon's gown and gloves should all be changed after the wound débridement. Rigid stabilization of the fracture increases patient comfort, improves blood supply to the tissues, facilitates wound healing, and promotes resistance to infection.

A number of techniques can be used for fracture repair. In general, after surgical débridement type I open fractures can be treated in the same manner as a closed fracture. Higher-grade open fractures require special consideration when planning repair. External coaptation with splints and casts is rarely appropriate since wound care is difficult and stabilization is generally inadequate. Use of intramedullary pins is avoided if possible, because they impede medullary circulation, may spread bacteria through the medullary cavity, and when used alone do not provide

rigid stabilization. Bone screw and plate fixation can be used, but placement of a large metallic foreign body at the fracture site is a disadvantage. Implants potentiate bacterial proliferation because the surfaces become covered with glycolipid, which allows *Staphylococcus* spp. and other gram-positive organisms to adhere. The extensive open surgical approach required for bone plating also further compromises vascularity. Despite these limitations, rigid fixation with a bone plate and screws is generally acceptable and usually results in uncomplicated healing.

External skeletal fixation is generally the fixation technique of choice, since fixation pins can be placed away from damaged tissue and rigid stabilization is possible. External skeletal fixation is economical, readily available, and does not require specialized equipment. The wound can be visualized and treated as needed. The Ilizarov ring external skeletal fixator may be particularly useful in these patients because very small fixation pins under tension are used.

Autogenous cancellous bone grafts are indicated in many open fractures, since cortical defects are common and these fractures may heal slowly because of vascular and soft-tissue damage. Transplanted cancellous bone facilitates bone healing by means of osteoconductive, osteoinductive, and osteogenic properties. Cancellous bone grafts rarely become infected, and, when they do, they undergo harmless liquefactive necrosis. The graft should be collected with a separate set of equipment and gloves to avoid contamination of the graft site. Alternately a combination of cancellous allograft and demineralized bone matrix providing osteoconductive and osteoinductive properties can be obtained commercially (Osteo-Allograft Mix, Veterinary Transplant Services). In severely avascular wounds bone grafting should be delayed 1 to 2 weeks to allow sufficient proliferation of granulation tissue to provide vascular support for the graft. If delayed grafting is performed, the incision should be through previously undamaged tissue if possible. Although cortical allografts have been used successfully in open fractures, they are not recommended, because the risk of sequestration and resorption is high. Autogenous vascular bone grafts transplanted by microsurgery may prove beneficial in the future.

WOUND CLOSURE

Wound closure can be performed if débridement results in a surgically clean wound with adequate vascularity that can be closed without tension. Dead space drainage should be accomplished with aseptically placed closed suction drains. In general, more severe type II and all type III open fractures should be handled as open wounds with delayed primary or secondary closure. If there is any doubt, it is always better to leave the wound open.

Thoracic Trauma

SCOTT P. SHAW, *North Grafton, Massachusetts*

Thoracic injury is common in dogs and cats following trauma. Thoracic trauma rarely occurs in isolation; patients frequently have other significant injuries that must be assessed. It has been estimated that 10% of all dogs presenting to the emergency room suffer from thoracic trauma severe enough to result in respiratory compromise. Common causes of thoracic injury include both blunt trauma, most commonly the result of a motor vehicle collision, and penetrating trauma, most commonly the result of bite wounds or projectile injury. Regardless of the cause of the injury, the clinician must be sure to perform a complete and thorough physical examination to ensure that no significant injuries are overlooked.

INITIAL APPROACH TO PATIENTS WITH THORACIC TRAUMA

One of the most challenging aspects of addressing patients with severe respiratory distress is their limited tolerance for stress. In some cases this may limit the clinician's ability to complete a thorough assessment until the patient's condition stabilizes. During the initial or primary survey the clinician should visually assess the patient from a distance. The observer should note the degree of distress, as well as the patient's respiratory rate and pattern and any noise. Changes in the respiratory pattern may signal further deterioration in patient condition, particularly if a breathing pattern characterized by an extended neck and short shallow breaths develops.

The observer should continue to assess the patient by auscultating and palpating the thorax. Lung and heart sounds should be auscultated bilaterally. Muffled heart and/or lung sounds may be heard in patients with pneumothorax, hemothorax, or diaphragmatic hernia. Crackles or increased adventitious sounds may indicate the presence of pulmonary contusions. The thorax should then be palpated. The clinician should look for injuries to the skin over the thorax and cranial abdomen, the presence of subcutaneous emphysema, and the loss of chest wall integrity caused by rib fractures.

Initial treatment for any patient with signs of respiratory distress should include oxygen supplementation. Options for oxygen supplementation include flow-by/face mask, the placement of nasal oxygen lines, the use of an oxygen cage, and in the most severe cases intubation and mechanical ventilation.

RADIOGRAPHIC ASSESSMENT OF THE ANIMAL WITH THORACIC TRAUMA

Survey thoracic radiographs are indicated in all patients with a history of moderate-to-severe trauma. However,

thoracic radiographs should not be performed as part of the initial survey because many animals with respiratory impairment cannot handle the stress associated with radiography.

Once the patient is deemed stable for radiographs, two views should always be obtained. The clinician should evaluate the radiographs for diaphragmatic integrity, pulmonary infiltrates, the presence of pneumothorax, and rib and/or spinal fractures.

PULMONARY CONTUSIONS

Pulmonary contusions consist of hemorrhage and high-protein edema fluid that fill the alveoli. These are perhaps best thought of as bruises of the lung parenchyma. When the thoracic wall is struck, it initially absorbs the force of the impact. As the thoracic cage is compressed, the underlying lung parenchyma collapses and compresses. Once the compressive force is removed, the elastic recoil of the thoracic cage results in decompression of the parenchyma. This rapid compression-decompression results in rupture of the alveoli and alveolar capillaries. Subsequently hemorrhage and edema fluid fill the alveoli.

Clinical signs of pulmonary contusions include respiratory distress, hemoptysis, orthopnea, and cyanosis. Radiographically pulmonary contusions manifest themselves as a patchy interstitial-to-alveolar pattern that is generally worse on the side of impact and may be surrounded by pneumothorax. The radiographic changes associated with pulmonary contusions tend to worsen over the first 24 hours after injury, regardless of the patient's clinical course. In general, patients with life-threatening pulmonary contusion will present with moderate-to-severe respiratory distress.

Treatment of animals with pulmonary contusion is mainly supportive. The majority of animals with pulmonary contusions improve with oxygen supplementation and supportive care while other injuries are evaluated and treated. The most severe cases may require mechanical ventilation. Only 1% of dogs with pulmonary contusion go on to develop bronchopneumonia. Therefore prophylactic antimicrobial therapy is not indicated.

There is ongoing controversy concerning the optimal fluid therapy for patients with pulmonary contusions. There is considerable experimental evidence that overhydration results in worsening of pulmonary contusions. There is also some evidence that colloids may remain in the pulmonary interstitium for prolonged periods of time, leading to slower resolution of the contusions. As a result of these concerns, *judicious use of crystalloid fluids* seems most appropriate. It is also important that the clinician

not underresuscitate the patient because of fear of worsening the pulmonary contusions.

The prognosis for dogs with pulmonary contusions varies widely. Animals that present with mild-to-moderate respiratory distress are very likely to recover. Patients with severe respiratory distress, particularly those requiring mechanical ventilation, warrant a more guarded prognosis.

PNEUMOTHORAX

Pneumothorax is the accumulation of air in the space between the lung parenchyma and muscles of the thoracic wall. Pneumothorax can be classified as either open or closed. Open pneumothorax is characterized by a disruption of the thoracic wall, which allows air to enter into the pleural space. Small-volume pneumothorax may result in no clinical signs and require no treatment, whereas large-volume pneumothorax may require rapid identification and treatment to save the patient.

Pneumothorax from thoracic trauma results from a sudden increase in airway pressure. This, combined with shear forces applied to the lung parenchyma, results in alveolar rupture and leaking of air into the pleural space. In cases of sharp, penetrating trauma direct disruption of the pulmonary parenchyma may result in the development of pneumothorax.

Given the relatively fixed volume within the thoracic cage, patients with pneumothorax have a decrease in tidal volume. Generally minute ventilation is maintained by an increase in the respiratory rate. In severe cases of pneumothorax minute ventilation falls to the point that hypoxemia develops. The most severe form of pneumothorax is a tension pneumothorax. A tension pneumothorax results when there is an increase in the volume of pneumothorax with each inspiration through a one-way flap. When intrapleural pressure exceeds alveolar pressure, the lung lobes on that side of the thorax collapse. There is a rapid decline in respiratory status, and respiratory arrest will develop if emergency therapy is not initiated.

Treatment of pneumothorax requires either percutaneous needle thoracocentesis or the placement of a thoracostomy tube (also see Chapter 154). Patients with a history of trauma and physical examination findings consistent with a pneumothorax frequently benefit from thoracocentesis before obtaining thoracic radiographs. In these patients the potential benefit far outweighs the minimal risk posed by percutaneous needle thoracocentesis in trauma patients. A thoracostomy tube should be considered in animals in which multiple needle thoracocentesis fail to achieve resolution, no end point is reached during needle thoracocentesis, or the patient requires positive-pressure ventilation.

DIAPHRAGMATIC HERNIA

A diaphragmatic hernia occurs when intraabdominal pressure exceeds abdominal pressure, such as might occur during blunt trauma. Many patients with a diaphragmatic hernia have paradoxical abdominal motion during respiration (abdomen is sucked in on inspiration). In addition, the abdomen may feel “empty” on palpation. Thoracic radiographs may provide evidence supportive of the diagnosis.

Gastric or bowel gas patterns crossing the plane of the diaphragm make the diagnosis simple, but gastrointestinal structures are not always misplaced. Pleural fluid or tissue can impair the ability to see the diaphragm completely; therefore additional techniques such as thoracic ultrasound may be required to confirm the diagnosis. Ultrasonography may be able to define borders of soft-tissue structures such as spleen or liver traversing the diaphragm.

Initial treatment of a patient with a diaphragmatic hernia involves stabilization of its cardiovascular and respiratory status. Patients with severe respiratory distress frequently have a large percentage of their abdominal contents within the thorax. In these cases mechanical ventilation may be needed to correct hypoxemia.

Correction of a diaphragmatic hernia requires surgery. In general, surgical intervention should be pursued as soon as the patient is stable. Historically it had been recommended that intervention be postponed for at least 24 hours; however, more recent investigation has supported intervention once the patient is stable.

FLAIL CHEST

Flail chest is defined as the paradoxical movement of a floating thoracic segment. This occurs when there is a fracture of two or more consecutive ribs in two places (ventral and dorsal). Paradoxical movement results from the changes in intrapleural pressures. On inspiration intrapleural pressure decreases, and the lungs and thoracic cage expand. Because of the instability of the flail segment, it does not move outward with the rest of the thoracic wall; instead the flail segment moves inward (toward the more negative pressure). The reverse is true on expiration. The combination of concurrent pulmonary contusion and pain can predispose to hypoxemia and hypoventilation.

Treatment should initially focus on relieving the pain caused by the flail segment. Placing the flail segment down helps to limit the motion, thus decreasing pain. Intercostal nerve blocks can be very effective at limiting the pain. Mechanical stabilization of the flail segment is rarely needed and only indicated in the most severe cases.

Intravenous Anesthetic and Analgesic Techniques

THOMAS K. DAY, *Louisville, Kentucky*

Intravenous continuous (constant)-rate infusions (CRIs) are commonly used in dogs and cats to maintain anesthesia after induction. The CRI is optimal for all-injectable anesthesia techniques and also is applicable to the continuous administration of analgesic drugs. When using a CRI for an all-injectable anesthesia, several anesthetic drug combinations are likely to be needed and are more likely to maintain anesthesia safely when compared to a single agent. Furthermore, species differences between dogs and cats warrant special mention when administering all-injectable anesthesia.

Choices of anesthetic drugs applicable to critically ill dogs and cats are limited. Long-acting sedatives such as acepromazine should be avoided in most instances. However, if the dog or cat is hemodynamically stable, small doses of acepromazine (0.025 to 0.05 mg/kg IV) can be administered to control excessive excitement or dysphoria. Although useful for analgesia (see Chapter 2) in general the α -2 agonists should be avoided in critically ill dogs and cats since these drugs can cause further cardiopulmonary compromise.

Opioids alone or in combination with the local anesthetic lidocaine and the dissociative drug ketamine can be used to provide anesthesia and analgesia in many critically ill dogs and cats. Many combinations are available, and it is the decision of the clinician as to which CRI to administer. Decisions generally can be made based on severity of postoperative pain, species, procedure to be performed, and experience of the clinician.

The choice of drugs used in a CRI depends on many factors, including species, age, the procedure to be performed; and the physical status of the dog or cat. A “cook book” plan for administration of anesthetics and analgesics to critically ill dogs and cats is discouraged. The clinician should individualize the anesthetic protocol to maximize efficacy and safety. This chapter describes a number of proven CRI methods applicable to dogs and cats in the critical care setting.

CONTINUOUS-RATE INFUSIONS FOR DOGS

Morphine

Morphine is the prototype opioid used for analgesia. A morphine CRI (0.1 mg/kg/hour) provides excellent continuous analgesia in dogs. However, a morphine CRI used alone will likely not provide a level of sedation that is adequate. Appropriate preanesthetic medication (opioids or

neuroleptanalgesia) and induction of anesthesia with any agent followed by a morphine CRI may provide adequate short-term anesthesia in dogs.

Morphine-Lidocaine-Ketamine

This morphine-lidocaine-ketamine (MLK) “cocktail” works very well in dogs and minimizes some of the effects of high dosing of just one or two of these drugs. The local anesthetic lidocaine results in moderate central nervous system (CNS) depression, which, when combined with morphine, results in more reliable sedation than morphine alone. The amount of ketamine added in this combination does not stimulate the CNS but is very helpful for the prevention of wind-up pain. As with a morphine CRI, appropriate preanesthetic medication (opioids or neuroleptanalgesia) and induction of anesthesia with an intravenous agent, followed by an MLK CRI, provides reliable short-term anesthesia in dogs. To create an MLK infusion, the following drugs are added to a 1-L bag of lactated Ringer’s solution (LRS): morphine (1.8 ml of a 15-mg/ml concentration), lidocaine (15 ml of 2% or 20-mg/ml concentration); ketamine (0.6 ml of a 100-mg/ml concentration). The initial administration rate is typically the usual anesthesia rate of crystalloid fluids (10 ml/kg/hour). The administration rate for analgesia following the surgical procedure is 2.5 ml/kg/hour.

Fentanyl

Fentanyl is approximately 100 times more potent than morphine and provides more reliable CNS depression. A fentanyl CRI (5 to 10 mcg/kg/hour) can provide excellent analgesia. A higher infusion rate (10 to 40 mcg/kg/hour) can result in surgical analgesia. The critically ill dog requires much less than a normal dog. Fentanyl has a very short half-life (minutes) and is ideal for inclusion as a CRI.

Fentanyl-Lidocaine-Ketamine

The addition of lidocaine to fentanyl, as with MLK, can result in profound CNS depression and more reliable sedation and anesthesia. The amount of ketamine does not create CNS side effects. To create a fentanyl-lidocaine-ketamine (FLK) infusion, the following drugs are added to a 1-L bag of LRS: lidocaine (15 ml of 2% or 20-mg/ml concentration); ketamine (0.6 ml of a 100-mg/ml concentration), and fentanyl. The volume

of fentanyl (50 mcg/ml concentration) varies based on the rate of fluid administration. In general, a CRI of 3 to 5 mcg/kg/hour should be prepared for administration. The fluid rates are similar to those used for MLK preparations. Adjusting a prepared bag of FLK can be difficult. Alternatively the lidocaine and ketamine can be delivered as previously described, and fentanyl can be delivered via a syringe pump. The clinician can make the desired concentration of fentanyl and change the rate of fentanyl infusion with ease.

Propofol

Propofol is classified as a phenolic compound and is unrelated to opioids, barbiturates, or steroid anesthetics. Propofol induction is characterized as a very rapid and smooth induction with a very rapid and smooth recovery. Noncumulative effects make propofol an ideal drug for CRIs, provided the patient is not suffering from severe cardiovascular depression since propofol is a negative inotrope. Use of preanesthetic medication greatly reduces the dose of propofol required for induction and maintenance of anesthesia. Induction with propofol (1 to 5 mg/kg IV) followed by a CRI (0.14 to 0.4 mg/kg/minute IV) can result in long-term sedation for minimally invasive procedures. The level of sedation achieved depends on the preanesthetic medication and the achieved effect. Higher infusion rates are required to maintain a surgical plane of anesthesia and to maintain an endotracheal tube since propofol can result in significant respiratory depression. Another drawback is cost; a propofol CRI can become very expensive in a larger dog.

CONTINUOUS-RATE INFUSIONS FOR CATS

CRIs of opioid combinations for cats are prepared and administered differently than for dogs. Cats are more likely to have adverse effects from lidocaine, including seizures and hypotension. Therefore lidocaine is not used in these combinations. Furthermore, cats can become excited or dysphoric from opioid combinations and are less likely to become overtly sedated when compared to dogs. A tranquilizer such as acepromazine (0.025 mg/kg IV) or a sedative such as diazepam (0.2 mg/kg IV) can be useful to minimize side effects caused by opioids. Acepromazine must be used with caution if at all in cats that are hypotensive, bradycardic, or hypothermic.

Morphine

A morphine CRI in cats produces minimal sedation unless the cat is severely depressed. The infusion rate (0.1 mg/kg/hour) is similar to that for dogs, and neuroleptanalgesia or sedation is required to maintain the desired level of anesthesia.

Morphine-Ketamine

Morphine (1.8 ml of a 15-mg/ml concentration) and ketamine (0.6 ml of a 100-mg/ml concentration) (MK) are added to a 1-L bag of LRS. Alternatively one fourth of each drug can be added to a 250-ml bag of LRS. The initial administration rate is typically the anesthesia rate of fluids (10 ml/kg/hour) after induction of anesthesia. An administration rate of 2.5 ml/kg/hour is typical following the procedure.

Fentanyl-Ketamine (FK)

Ketamine (0.6 ml of a 100-mg/ml concentration) is added to a 1-L bag of LRS. The volume of fentanyl (50-mcg/ml concentration) will vary based on the rate of fluid administration. A volume to provide a CRI of 3 mcg/kg/hour should be prepared for use during the procedure following induction of anesthesia. The fluid rates are similar to those used for MK preparations, and the amount of fentanyl will be different for each rate. Alternatively the ketamine can be administered alone, and the fentanyl can be administered via syringe pump for ease and safety.

Propofol

Propofol can be administered in a similar fashion as described above for dogs. The induction and maintenance dosage will vary based on the drugs used for preanesthetic medication and induction. A common practice would be to induce anesthesia with propofol (1 to 3 mg/kg slow IV bolus) followed by a CRI (0.1 to 0.3 mg/kg/minute). The amount of propofol used will likely be much less than for larger dogs and should be more economical. Infusions lasting more than 30 minutes can result in a longer recovery than the same infusion time in dogs because cats metabolize propofol slower. The airway should be controlled when procedures are long. Consecutive-day infusions of propofol (for radiation therapy, wound management) can result in Heinz body production and possibly Heinz body anemia in cats.

Pet Food Safety

Toxin Exposures in Small Animals

LYNN R. HOVDA, *Bloomington, Minnesota*

The Pet Poison Helpline (PPH) is a division of SafetyCall International that began fee-for-service animal toxicology and poison information in 2004. The helpline is available to animal owners, veterinarians, veterinary students, veterinary technicians, pesticide control officers, and others 24 hours a day, 7 days a week for a one-time fee. The line is staffed by veterinarians, certified veterinary technicians, veterinary students, pharmacists, pharmacy students and technicians, medical doctors, zoologists, and others with specialized knowledge in fields such as reptiles and snakes.

During the 12-month period beginning July 1, 2005 and ending June 30, 2006, the PPH received over 9000 animal toxicology calls. The distribution of these calls is presented as a sampling of animal toxicology questions posed to small animal practitioners. The source of these calls, species affected, age of animals, and toxin types are briefly summarized.

About 70% of calls originated from pet owners, and 20% from veterinarians or veterinary hospitals or clinics. The remaining calls came from a myriad of sources, including zoological gardens, farms and ranches, restaurants, and stores.

Dog exposures accounted for about 88% of the calls, with cats accounting for 10%, and other species the remaining 2%. Animals included as other species were primarily caged birds and pocket pets (sugar gliders, rabbits, and small rodents) with a few potbellied pigs, goats, and horses.

Most of the calls involved animals in the younger age-group. Of canine-related calls, 79% were in the 5 years and under age-group, with 17% in the 6- to 12-year age range. Very few calls involved dogs in the 13- to 19-year age range. Cat-related calls involved 62% in the 0- to 5-year age range, and 23% in the 6- to 12-year age range. No age-related data were retrieved for the other animal calls.

There were 1831 calls pertaining to mixed breeds, followed in decreasing order by these breeds: the Labrador retriever (884), golden retriever (291), Yorkshire terrier (234), Chihuahua (232), and boxer (196). Cats were split between domestic shorthair, domestic longhair, and mixed breed or unknown.

Twenty-two deaths were recorded during the 12-month period (Table 18-1). This number may be falsely low because some cases had an unknown or undocumented outcome. Fifteen dogs, three cats, two birds, one pocket pet, and one horse died or were humanely euthanized. Two calls originated from offices or hospitals, and the

rest from homes or farms. The most common cause of death in all species was from pesticides or other products used around the house and garden to eliminate insects, rodents, or weeds (8), followed by human drugs (4), and unknown toxins (4).

For the purpose of investigating the specific call type, calls were divided into eight general categories (Table 18-2). Subdivisions were used in each category as needed to further classify information.

Almost all of the calls involving plants and mushrooms (563 total calls) originated from the caller's home or personal residence. When corrected for increasing monthly volume, the number of calls per month was relatively steady across the calendar year. Two small spikes occurred: one in December when the number of poinsettia calls increased and one in April associated with an increase in Easter lily calls. Other common plant calls included azalea, sago palm, marijuana, cyclamen, lilies of all varieties, and all varieties of oxalate-containing plants. Over 60% of the plant ingestions involved symptomatic cats and were primarily associated with some form of lily or oxalate-containing plant. Sago palm and marijuana exposures were limited to the dog population.

Over 4000 human drugs and herbal supplements were identified as potential toxins. This number does not reflect the actual call volume because multidrug ingestions occurred with some frequency and were generally associated with the most serious and life-threatening ingestions. Within this category human prescription drugs constituted about 66% of calls, while exposure to over-the-counter (OTC) drugs and nutraceuticals constituted about 33% of the calls. Oral products accounted for almost all of the human prescription drug exposures, with ingestion of very few topical, patch, suppository, lollipop, or inhaled substances. Within the human prescription drug division, antidepressant drugs, antianxiety drugs, newer sleep-inducing drugs, drugs for attention-deficit disorder, and cholesterol-lowering drugs were overrepresented. Despite the large number of calls generated by these drugs, few serious outcomes occurred. Three of the drug-related deaths were from ingestion of topical products (5-fluorouracil and calcifediol) that were reported less than 14 times in the 12-month period. OTC drugs and nutraceuticals showed a slightly different picture, with about 10% of the ingestions involving topical medications and ophthalmic solutions. Within this category pain medications such as acetaminophen (APAP), aspirin, ibuprofen, and naproxen were the drugs most commonly ingested, followed by

Table 18-1

Category of Deaths

Category	Number of Calls
House and garden	8
Insecticide (4)	
Zinc phosphide (2)	
Rodenticide (1)	
Herbicide (1)	
Unknown	4
Human drugs (prescription and over-the-counter)	4
Household products	2
Foreign bodies	2
Other	2

cough and cold products, multivitamins, herbal supplements, and calcium-containing supplements. With the exception of pain medications, clinical signs in this group were generally mild and self-limiting. One drug-related death occurred from a massive dose of ibuprofen.

Surprisingly, silica gel packets made up over 50% of the calls falling into the foreign body category. With the exception of one cat that ate a dryer sheet, all of the calls involved dogs, in particular Labrador retrievers and golden retrievers. Other common foreign body ingestions included batteries of all types, pens, pencils, fireplace starter logs, coins, and glues. Some of the more interesting items ingested included a stuffed alligator head, three forks, 40 pennies, a safety razor, a light bulb, and a lead x-ray glove.

Exposures involving household products were equally split between dogs and cats. The exposures were easily divided into those involving laundry products, general cleaning products, toilet products, and carpet-cleaning or carpet-freshening products. When further analyzed, cat exposures occurred most often in the laundry and bathroom area, whereas dogs ingested carpet-freshening agents and general cleaning products more often. Clinical signs in this category for all species were usually mild and self-limiting.

Of the 531 food-related calls, over half of them involved dogs ingesting some form of chocolate. This was con-

sistent for each and every month. Other food products included nuts (almonds, macadamia nuts, and hazelnuts), onions, grapes and raisins, and xylitol-containing gums. When corrected for increasing call volume, a distinct increase occurred in December and again in late March and early April. Butter, gravy, meat products, and eggnog ingestions all increased in December, presumably because of increased availability and decreased surveillance. The number of chocolate and candy ingestions increased around Easter, again presumably because of the increased availability.

Almost 1800 calls involved exposures to house, lawn, and garden products. Included were products meant to eliminate insects and other pests or rodents, herbicides, and fertilizers. Pyrethrin-based insecticides accounted for over 80% of the insecticide calls, followed by avamectin or ivermectin, imidacloprid, and boric acid. Outcomes in this group varied from none to severe, with cats having the most severe symptoms. Calls regarding a carbamate, organophosphate, or arsenic compound occurred much less frequently, but the outcome was generally much more severe. Deaths in the insecticide group (three dogs, one pocket pet) were from exposure to either a concentrated product or very large amounts of a more dilute product. A genuine seasonal occurrence occurred with these calls, with the incidence highest in summer and lowest in winter.

All of the rodenticide calls concerning ingestion of long-acting anticoagulant agents occurred in dogs. Most of the calls originated from the caller's home and were managed with no clinical signs. Calls originating from a health care facility were often associated with more severe clinical signs and required prolonged care and treatment. Despite aggressive medical care, one dog died from a brodifacoum overdose. Brodifacoum ingestions occurred with the most regularity, and the call number varied little from month to month. The remainder of the long-acting anticoagulant calls included difethialone, diphacinone, bromethalin, and bromadiolone. Three or four calls each month involved some form of sticky board exposure and typically involved cats or small dogs.

Household herbicide and fertilizer calls were almost always of low toxicity and involved a taste, touch, or lick of a product or ingestion of treated grass. Rarely did any clinical effects develop, and signs that occurred involved primarily vomiting and other gastrointestinal signs. One cat death did occur from the ingestion of a liquid herbicide. There was a distinct seasonal occurrence to these calls, with lowest call volume in December and January and the highest in early spring and summer.

Zinc phosphide, although technically a pesticide, was counted separately because calls related to this product were almost always associated with a moderate-to-severe clinical outcome. This product is placed below ground in gopher or other small rodent holes, under mobile homes, or in other below-ground areas. In addition to the inherent toxicity, the product is often placed and forgotten until dug up and ingested by a curious dog. Two documented deaths occurred. Although primarily a problem in dogs, one horse died from eating a large amount of product from a bucket in the back of a pesticide control officer's truck.

Table 18-2

Classifications of Call Type

Call Type	Yearly Call Volume
Human drugs and nutraceuticals	4108
Pesticides: insecticides, rodenticides, fertilizers, herbicides, others	1793
Plants and mushrooms	563
Food	531
Veterinary products	513
Foreign bodies	437
Household products	420
Other	1302

Dogs and cats were equally represented in calls involving veterinary products. Topical flea and tick products, including pyrethrin-based products, showed a seasonal occurrence, whereas nonsteroidal antiinflammatory drug ingestion was steady from month to month. Clinical signs and outcomes were worse with pyrethrin-based flea products, especially in cats. Other calls, primarily dog calls, included heartworm medication, prescription animal drugs, anthelmintics, and nutraceuticals. Clinical effects for almost all of these categories were mild and self-limiting.

The remainder of the calls were lumped into a large "other" category. Within this group several subdivisions emerged. Automotive products were the most prevalent, with more than 150 exposures in the 12-month period. Of these, 16 were known exposures to ethylene glycol. Fortunately no reported deaths occurred. This may be the result of early and aggressive care, the introduction of easy-to-use in-house ethylene glycol testing kits, or the availability of an antidote. Personal care products such as shampoos, nail polish remover, deodorants, and other items accounted for numerous calls but were all of low toxicity and generally resulted in few clinical effects. Oddly, animal and insect bites or stings occurred year-round, with two to three calls occurring each month. The outcome was generally good, and clinical signs were mild to moderate.

It is interesting to note that, even though dog exposures made up the vast majority of calls, clinical effects were usually mild, and the outcome was excellent. Despite the smaller number of calls, cats seemed to have a more difficult time with ingestions, and the outcome often was not as good. This may be because of their environment and their ability to crawl into smaller places, as well as their

inquisitive nature, relatively smaller body size, longer life span, or simple differences in metabolic pathways.

In summary, the PPH handled over 9000 calls, with 22 reported and documented deaths. The majority of calls originated from the caller's home, generally had no-to-few clinical signs, and were treated at home with no referral to a health care facility. About 88% of the calls involved young dogs, followed by cats and a variety of other species. The most common reported exposure was to human pharmaceuticals and OTC drugs/nutraceuticals, followed by pesticides and other agents used in the lawn and garden.

Toxin Exposures and Treatments: A Survey of Practicing Veterinarians

KELLY HALL, *St. Paul, Minnesota*

A survey to gather information from veterinarians on common small animal toxin exposures and treatments was created via a collaborative effort between the University of Minnesota (Drs. K. Hall and M. Murphy) and the Veterinary Information Network (VIN) (Dr. M. Rishniw and colleagues). The survey was available online for VIN members to respond to for approximately 2 weeks in September 2006. There were 160 responses representing veterinarians from the United States (81.3%), Canada (8.1%), Australia (5%), United Kingdom (1.2%), and other countries (4.4%). Table 19-1 indicates the geographic distribution of respondents from the United States and Canada. Respondents selected the type of practice in which they work (Fig. 19-1). Responses included general practice (71%); emergency-only practice (13%); referral practice with emergency service (12%); general practice with emergency service (1%); university hospital (1%); and one respondent each for house call/acupuncture, 95% feline practice, relief veterinarian, and referral/general practice (2%). Respondents' qualifications (156 respondents) included DVM (83%), ABVP (5%), ACVECC diplomats (3%), MS or PhD (3%), non-ACVECC diplomats (2%), and other (4%, internship and residency trained, RN, MPVM).

The survey questions are listed in Box 19-1. Survey results are available for VIN members to view on the Internet at <http://www.vin.com/Members/Library/>.

COMMON EXPOSURES

Dogs

More than 50% of respondents selected anticoagulant rodenticide, ingestion of chocolate, and animal envenomation as the most common exposures seen in dogs. The top 10 selected toxins are listed in Table 19-2. Additional toxins that were chosen less frequently included bromethalin (12%), acetaminophen (9%), cholecalciferol (4%), cholinesterase inhibitors (4%), zinc (3%), grapes/raisins (2%), Gorilla Glue (2%), ethanol (2%), lead (1%), methanol (1%), gasoline (1%), soap/detergent (1%) and bleach (0). Toxins not included on the list that were mentioned by respondents included coffee, blue-green algae, ivermectin, strychnine, xylitol, and tremorgenic mycotoxin.

Of the 51% of respondents who chose animal envenomation as a most common exposure in dogs, bee or

wasp (82%), snake (69%), and spider (38%) were most commonly selected; toad (9%) and scorpion (8%) were selected less frequently. Tick paralysis and ant swarms were each written in twice by respondents for the "other" category.

Of the 22% respondents who chose plant intoxication as a most common exposure, lily (66%), garlic/onion (32%), azalea (29%), and dieffenbachia (dumbcane) (24%) were most commonly selected from plants listed. Approximately 37% of respondents selected "other," including sago palm, mushroom, and oleander. Answers listed on the survey chosen least frequently included nightshade (5%), Japanese yew (5%), and bleeding heart (0).

Cats

More than 50% of respondents selected pyrethrin/permethrin and plant intoxication as the most common exposures seen in cats. The top 10 selected toxins are listed in Table 19-3. Toxins not included on the list included potpourri, oils (petrol, tea tree, lamp), macadamia nut, and paint/paint thinner. Additional toxins that were available for respondents to select from but were chosen less frequently included drugs of abuse (5%), soap/detergent (5%), bromethalin (3%), methalddehyde (3%), ethanol (2%), cholecalciferol (1%), bleach (1%), chocolate (1%), zinc (1%), lead (1%), methanol (gasoline 1%), gasoline (1%), grapes/raisins (0), and Gorilla Glue (0).

Of the 40% respondents who chose animal envenomation as a most common exposure in cats, bee or wasp (69%) and snake (61%) were most commonly selected; spider (18%), scorpion (2%), and toad (1%) were selected less frequently. Tick paralysis and skink/small lizard were each written in by respondents for the "other" category.

Of the 66% of respondents who chose plant intoxication as a most common exposure, lily ingestion far outweighed all other answers (90%). Additional answers included azalea (22%), dumbcane (21%), and garlic/onion (12%). Approximately 7% of respondents selected "other" and most frequently listed houseplants with oral and gastrointestinal topical effects (e.g., oxalates). Answers listed on the survey that were chosen least frequently included nightshade (3%), bleeding heart (2%), and Japanese yew (1%).

Table 19-1
Regional Data From Question 2: "If you live in the United States or Canada, please enter your ZIP code."

Region	Respondents
United States (119 of 130 Respondents)	
Northeast (21)	New York (8), Pennsylvania (5), Ohio (5), Maryland (3)
Southeast (22)	North Carolina (6), Virginia (5), Florida (5), Georgia (4), West Virginia (1), South Carolina (1)
South (17)	Texas (7), Tennessee (2), Alabama (2), Mississippi (2), Louisiana (2), Arkansas (1), Oklahoma (1)
Midwest (18)	Wisconsin (5), Iowa (5), Minnesota (3), Michigan (2), Illinois (2), Missouri (1)
West (40)	California (23), Oregon (5), Colorado (5), Washington (2), Idaho (2), Utah (2), Arizona (1)
Noncontinental (1)	Alaska (1)
Canada (11 of 13 Respondents)	
East (7)	Ontario (6), Prince Edward Island (1)
West (4)	British Columbia (2), Alberta (2)

DECONTAMINATION

Dogs

Apomorphine was selected overwhelmingly (69%) as the method of choice for inducing emesis when clinically indicated in dogs (Fig. 19-2). Hydrogen peroxide (26%) was selected second most frequently. Xylazine, syrup of ipecac, morphine, and "I don't induce vomiting" were each selected less than 2% of the time. Of the options listed in the survey, medetomidine was never selected.

Cats

Fig. 19-3 illustrates respondents' selection for method of choice for inducing emesis when clinically indicated in cats. Hydrogen peroxide (29%), xylazine (24%), and apomorphine (22%) were selected most frequently. "I don't induce vomiting in cats" was selected by 14% of respondents. Medetomidine (5%), morphine (4%), and syrup of ipecac (2%) were selected by the fewest respondents.

Fig. 19-1 Respondent's answer to question 3, "In what type of practice do you primarily work?"

HOSPITAL SUPPLIES

Decontamination

A majority of respondents stocked activated charcoal (98%), saline eye flush (86%), hydrogen peroxide (84%), apomorphine (79%), mineral oil (60%), and mild soap/detergent (59%) in their practice for decontamination purposes. Many respondents selected xylazine (44%) as supplied in their hospitals. Syrup of ipecac (9%) and sodium sulfate (3%) were selected least frequently (Fig. 19-4). Many respondents wrote in decontamination supplies

Survey Questions Posted on Veterinary Information Network for 2 Weeks

1. In which country do you live?
2. If you live in the United States or Canada, please enter your zip code.
3. In what type of practice do you primarily work?
4. The FIVE (5) most common toxin exposures in DOGS that present to my practice are:
5. If you chose "Animal Envenomation" in question 4, please specify.
6. If you chose "Plant Intoxication" in question 4, please specify.
7. The FIVE (5) most common toxin exposures in CATS that present to my practice are:
8. If you chose "animal envenomation" in question 7, please specify.
9. If you chose "plant intoxication" in question 7, please specify.
10. What is your method of choice for inducing emesis when clinically indicated? Which of the following do you keep stocked in your practice for toxin exposure decontamination?
11. Which of the following toxin antidotes do you keep stocked in your practice?
12. Which of the following supportive care/symptomatic therapy products do you keep stocked in your practice for uses including care of toxicity patients?
13. What equipment do you have for dealing with toxin exposure?
14. What is your highest level of veterinary training?
15. Additional comments about animal intoxication and this survey.

Table 19-2

Top 10 Responses for Question 4: "The FIVE (5) most common toxin exposures in DOGS that present to my practice are:"

Toxin	Percent Respondents
1. Anticoagulant rodenticide	89
2. Chocolate	54
3. Animal envenomation (e.g., insects, reptiles)	51
4. Nonsteroidal antiinflammatory drugs (e.g., carprofen, aspirin)	45
5. Human prescription medication	45
6. Ethylene glycol	32
7. Plant intoxication	22
8. Pyrethrin/Permethrin	22
9. Drugs of abuse (e.g., marijuana, cocaine)	18
10. Methaldehyde (snail bait)	16

Table 19-3

Top 10 Responses for Question 7: "The FIVE (5) most common toxin exposures in CATS that present to my practice are:"

Toxin	Percent Respondents
1. Pyrethrin/permethrin	86
2. Plant intoxication	66
3. Ethylene glycol	47
4. Acetaminophen	42
5. Animal envenomation (e.g., insects, reptiles)	40
6. Nonsteroidal antiinflammatory drugs (e.g., carprofen, aspirin)	39
7. Human prescription medication	34
8. Anticoagulant rodenticide	27
9. Cholinesterase inhibitors	9

Fig. 19-3 Respondent's answer to question 10 (cats), "What is your method of choice for inducing emesis when clinically indicated?"

Fig. 19-4 Respondent's answers to question 11, "Which of the following do you keep stocked in your practice for toxin exposure decontamination?" Respondents were able to select all that applied.

not listed on the survey, including baking soda, human oiling removal products (GoJo, Swarfega), table salt, morphine, medetomidine, sorbitol, and milk of magnesia.

Specific Therapies (Antidotes)

Atropine (95%) and vitamin K (91%) were stocked by most respondent’s clinics. Approximately half of respondents stocked ethanol (53%) and acetylcysteine (46%) (Fig. 19-5). Antidotes that were stocked less frequently included antivenin (27%), calcium ethylenediaminetetraacetic acid (EDTA) (23%), fomepizole (21%), 2-PAM (15%), calcitonin (10%), D-penicillamine (6%), and deferoxamine (2%). Other specific therapies not available on

the survey that were written in by respondents included methocarbamol, yohimbine, and naloxone.

General Therapies (Supportive Care)

A majority of respondents indicated that their practice stocked diazepam, atropine, furosemide, acepromazine, oxygen, dextrose, crystalloids, opioids, calcium, mannitol, cimetidine, cyproheptadine, β -blockers, phenobarbital, doxapram, naloxone, potassium chloride, and dopamine for uses that included supportive care of toxicity cases. Sodium bicarbonate, sucralfate, pentobarbital, oxyglobin, packed red blood cells, milk of magnesia, plasma, and vitamin C were stocked less frequently.

Fig. 19-5 Respondent’s answers to question 12, “Which of the following toxin antidotes do you keep stocked in your practice?” Respondents were able to select all that applied.

Fig. 19-6 Respondent’s answers to question 14, “What equipment do you have for dealing with toxin exposure?” Respondents were able to select all that applied.

Ammonium chloride was not selected by any respondents. Other general therapies not included on the survey list but written in by respondents included methocarbamol (also listed frequently in specific therapies for tremorogenic toxins, oral or topical), midazolam, whole blood, and misoprostol.

Monitoring and Treatment Equipment

Most respondents had glucometers (95%), pulse-oximeters (92%), gastric lavage tubing (90%), blood chemistry analyzers (87%), electrocardiographs (84%), charcoal administration sets (81%), electrolyte analyzers (74%), and indirect blood pressure monitoring (72%) available in their clinics. Fewer respondents listed urinary Foley catheters (45%), blood gas analyzers (32%), capnometers (31%), clotting time analyzers (30%), blood lactate monitors (24%) and direct blood pressure monitors (22%) as being available in their clinics. Central venous pressure manometry (7%), peritoneal lavage systems (6%), and

Swan-Ganz catheters (1%) were rarely selected as being available in their practice by respondents. Equipment not included on the survey list but written in by respondents included ventilators, warm blankets/cage floors, enema delivery systems, and endoscopy (Fig. 19-6).

OTHER RESOURCES

Numerous comments at the end of the survey included information on where practitioners liked to find toxicology information or the need for the availability of more concise/immediate information. Multiple excellent resources are available to help veterinarians and owners deal with toxin exposure in pets, including SafetyCall International's Pet Poison Helpline (1-800-213-6680), the ASPCA Animal Poison Control Center (1-888-4ANIMAL-HELP), emergency clinics, veterinary schools, veterinary diagnostic laboratories (www.aavld.org), and veterinarians who are board certified in emergency and critical care (ACVECCS) or as toxicologists (www.abvt.org).

CHAPTER 20

Reporting an Adverse Drug Reaction to the Food and Drug Administration

LYNN O. POST, *Rockville, Maryland*

A great deal of time and expense is invested by industry and regulators to test the safety and efficacy of animal drug products before marketing an approved drug. The concern for the safety and effectiveness of a drug does not end at drug approval. Veterinarians and consumers must have some assurance that the products they administer to pets and livestock are also safe and effective in the postapproval period. *Pharmacovigilance* is defined as the science and activities relating to the detection and interpretation of safety concerns to minimize risk and allow for appropriate regulatory action. The results of adverse drug event (ADE) monitoring and risk assessment must be made available to veterinarians and consumers as quickly as possible. The Food and Drug Administration (FDA) relies on spontaneous reports, (i.e., reports that are voluntary from veterinarians and consumers) to accomplish its pharmacovigilance tasks.

Making sense of ADEs is a "fuzzy world" (Edwards, 1997). Separating a true adverse reaction, known as a *signal*, from background noise is difficult. The evaluation of ADE data does not achieve the criteria imposed on traditional scientific studies involving less than 50 animals per sample. There are usually many confounding factors, a clearly defined control group is often lacking, and it is more difficult to test the hypothesis of a cause-and-effect relationship (Avorn, 2004). Rather the fuzzy world of ADEs is characterized by observational data in which associations are derived from hundreds-to-thousands of animals and dozens of confounding factors, including weight, age, sex, preexisting medical conditions, administration of other drugs, and the lack of a definitive control group or baseline. Absolute cause and effect cannot be determined in the ambiguous world of ADEs. On the other hand, the limitations of observational studies do not mean that proper enforceable inferences cannot be drawn from ADE data.

ADVERSE DRUG EVENT REPORTING SYSTEM FOR APPROVED ANIMAL DRUGS

Adverse Drug Event Regulations

An *adverse drug experience (ADE)* is defined as an association of a clinical sign with the use of a new animal drug, whether or not the sign is considered to be drug related and whether or not the new animal drug was used in accordance with the approved labeling (i.e., the product may have been used according to label directions or in an extralabel manner, including but not limited to a different route of administration, different species, different indications, or other than labeled dosage) (21 Code of Federal Regulations [CFR] 514.3). Adverse drug experience includes but is not limited to:

- An adverse event occurring in animals in the course of the use of an animal drug product by a veterinarian or a livestock producer or other animal owner or caretaker.
- Failure of a new animal drug to produce its expected pharmacologic or clinical effect (lack of expected effectiveness).
- An adverse event occurring in humans from exposure during manufacture, testing, handling, or use of a new animal drug.

The regulations that specifically address the spontaneous reporting obligations of the drug sponsors of FDA-approved animal drugs are contained in "Records and reports concerning experience with new animal drugs for which an approved application is in effect" (21 CFR 514.80). Approved animal drugs are codified in the Federal Register and the CFR with a new animal drug application number. Reporting of ADEs for approved animal drugs is mandatory for the animal pharmaceutical industry. Once the veterinarian or consumer reports the ADE to the company, it is mandatory for the company to forward the information to the FDA. It is voluntary for veterinarians and consumers to report the ADE to the company or directly to the FDA. Companies report the ADE on Form FDA1932. Animal ADEs can be reported directly to the FDA by the veterinarian or consumer by using Form FDA 1932a, which is a shortened version of Form FDA1932 (available on the Center for Veterinary Medicine [CVM] website: <http://www.fda.gov/cvm/adetoc.htm>).

Reporting Adverse Drug Events to the FDA, USDA, and EPA

ADE submission is required only from companies marketing FDA-approved animal drugs. There are no requirements for submitting ADEs for human drugs used in animals or unapproved products labeled for animals. The FDA, Center for Drug Evaluation and Research, will not accept ADEs pertaining to extralabel use of human drugs in animals. The CVM accepts reports directly from consumers and veterinarians regarding extralabel use of human drugs and unapproved animal drug products. The CVM has limited resources to monitor the performance of these drugs in animals.

ADE reporting to CVM has significantly increased over the last decade. During the early 1990s the CVM received approximately 1000 ADEs each year. The CVM received about 33,000 ADE reports for the year 2005. Reasons for the increase are numerous but include the new types of drugs approved for use in companion animals, label information provided for contacting drug companies, and the interest of the public in reporting perceived product problems.

Veterinarians are encouraged to report ADEs directly to the sponsor* who will fill out Form FDA 1932 for submission to the CVM. About 99% of the ADEs received by the CVM are submitted by the sponsor on Form FDA 1932. Less than 1% of reported ADEs are submitted directly to the CVM by the veterinarian or consumer (Form FDA 1932a). Another reporting option is to call the CVM ADE hotline (1-888-FDA-VETS) to report an ADE. An FDA veterinarian will return the phone call. The reporter can also either call or write the CVM to obtain a prepostage-paid reporting form. If the ADE is not a drug, the following contacts may be useful: United States Department of Agriculture (animal biologics), 800-752-6255, <http://www.aphis.usda.gov/vs/cvb/html/adverseeventreport.html>; Environmental Protection Agency (topical insecticides), 800-858-7378, <http://www.epa.gov/opp00001/health/pets.htm>.

ADE Reports From Animal Pharmaceutical Companies

For industry reporting the ADEs are divided into three categories: (1) significant product defect reports that should be submitted to an FDA District Office within 3 days (21 CFR 514.80 [b] [1]); (2) ADEs involving unexpected animal injury and unexpected product ineffectiveness that should be submitted within 15 working days to the CVM (21 CFR 514.80 [b] [2]); and (3) the remaining types of ADEs and product defects that should be submitted at periodic intervals to the CVM (21 CFR 514.80 [a] [4]). All categories of complaints are required to be submitted by the drug sponsor on the Office of Management and Budget (OMB)-approved Form FDA 1932 ("Veterinary Adverse Drug Reaction, Lack of Effectiveness, and Product Defect Report").

Significant product defects are those involving either label mix-ups or a significant departure of the product from approved specifications in which the product defect may result in immediate harm to animals. Product defects that may result in a serious ADE are reported by the manufacturer to the FDA field office within 3 days. Corrective action is accomplished through the FDA Field Office responsible for the manufacturing site. More benign product defects that do not have the potential for serious ADEs are reported in the annual report directly to the CVM.

ADEs requiring 15-day submissions are serious and unexpected (21 CFR 514.3 and 514.80). A serious ADE:

- Is fatal or life threatening,
- Requires professional intervention,

*Sponsor: owner of the approved new animal drug.

- Causes an abortion, stillbirth, infertility, or permanent disability disfigurement, or
- Is an unexpected ADE that is not on the current label or may be pathophysiologically related to an ADE on the label.

Unexpected refers to information that is not contained either on product labeling or as part of the approved FDA application. Regulations further require reporting of unexpected adverse events that are associated with clinical use, studies, investigations, or tests, whether or not determined to be attributable to the suspected drug. These regulations also apply to extralabel use of the drug. A key phrase is “whether or not determined to be attributable to the suspected drug.” The CVM expects the drug sponsor to submit all ADEs rather than only the reports that the firm believes to be associated with the ADE. The CVM considers selective report submission or filtering to introduce a bias that confounds the evaluation of submitted ADEs.

EVALUATION OF ADVERSE DRUG EVENT REPORTS

Adverse Drug Event Evaluation Algorithm

The CVM uses the modified Kramer algorithm to assign a causality score to each clinical sign in an ADE report (Hutchinson et al., 1979a, 1979b; Keller, Bataller, and Oeller, 1998). The causality assessment is a measure of an association and not cause and effect. The algorithm has six standardized criteria: (1) information from the scientific literature; (2) previous documentation of the clinical sign; (3) alternative explanations for the clinical sign; (4) timing of events and amount of the drug administered; (5) *dechallenge*, lessening of the clinical sign when the influence of the drug passes; and (6) *rechallenge*, reappearance of the clinical sign when the drug is given again.

This method uses a procedure that lends some objectivity to an otherwise very subjective process. The algorithm is applied to each clinical sign in an adverse event report. The numeric scores for each of the six criteria are summed to arrive at a causality assessment score. The numeric score is matched to one of the four general categories of drug-related associations consisting of: “Probable, Possible, Unlikely, and Unknown,” as outlined in Box 20-1 (EMA, 2004). All clinical signs with positive causality assessment scores in the “Possible and Probable” drug-related categories are transferred to the cumulative summary on the FDA CVM website. Clinical signs with negative causality assessment scores (“Unknown and Unlikely”) are not transferred to the CVM web site.

An ADE becomes an adverse drug reaction when one or more clinical signs in the ADE report are scored with a positive causality assessment. This means that there may be some association or relationship between the ADE and the drug. A positive causality score for one clinical sign from a single ADE report does not generate an instant label change or regulatory action by the CVM. A limitation of the modified Kramer algorithm is the skewing to a lower causality assessment to the level of “Unlikely” or

Box 20-1

Causality Assessment Categories*

Probable: All of the following should apply for probable:

- There should be a reasonable association in time between the administration of the animal drug product and the onset and duration of the reported event.
- The description of the clinical signs should be consistent with an adverse drug reaction, or at least plausible, given the known pharmacology and toxicology of the product.
- There should be no other equally plausible explanation of the case. In particular, concurrent use of other products and possible interactions or preexisting medical conditions should be taken into account in the assessment.

When any of the above criteria cannot be satisfied because of conflicting data or lack of information, such reports can only be classified as “possible, unlikely, or not applicable.”

- *Possible:* When the information suggests another possible explanation or plausible cause for the described event but the data do not meet the criteria for inclusion in the “Probable” category.
- *Unlikely:* When sufficient information exists to establish beyond a reasonable doubt that an animal drug product was not likely to be the cause of the event.
- *Unknown:* Unclassifiable or not assessable for cases in which insufficient information was not available to draw a conclusion to include all cases in which reliable data are unavailable or are insufficient to make an assessment of causality. The ADE could be related to the drug, but present data are not adequate to draw a conclusion. The category includes (1) inconclusive: cases in which other factors prevent a conclusion from being drawn but a product association cannot be discounted; and (2) unclassified: cases in which insufficient information did not allow a conclusion to be drawn.

*These definitions are not a substitute for a causality assessment process such as the modified Kramer algorithm. Each definition characterizes the level of certainty or uncertainty of the association between a drug and an adverse event.

“Possibly” drug-related from a more appropriate category of “Possibly or Probably.” This results from the difficulty of assigning a positive number (placing a clinical sign in the “Possible” or “Probable” category) (see Table 20-1) to an event that occurs a long time after rechallenge or dechallenge. Thus a low frequency of a specific clinical sign could be overlooked as background noise rather than a signal. This is especially true in regard to long-acting drugs such as heartworm preventives.

Advantages of Adverse Drug Event Reports

The main advantage of ADE reporting is that large, heterogeneous animal populations are available compared to small, homogeneous populations in preapproval studies. Drugs are evaluated under actual conditions of use as opposed to a controlled laboratory setting. Signal detection often depends on confounding factors or conditions of use. Once a signal has been detected and discussed by industry and regulators, risk can be identified early in the marketing history of a product. The alternative would be

to use thousands of animals in classical controlled studies, which would be cost prohibitive. It is unlikely that ADEs occurring at low frequencies would be manifested even in massive classical studies; in addition, these studies rarely duplicate actual conditions of use. On the other hand, signals generated by evaluation of ADE reports can be used to design classical studies to test hypotheses. The classical studies can corroborate or refute the observational studies that depend on ADE data.

Disadvantages of Adverse Drug Event Reports

It is difficult to calculate a true incidence for spontaneous ADE data. The numerator is underreported*; and the denominator, usually the number of doses administered, is almost never known. More severe clinical signs such as blindness and death are probably reported more often by veterinarians and consumers. A reporting rate can be calculated using the total number or frequency of clinical signs divided by the total number of ADE reports, but this is not a very useful number. Prospective epidemiologic studies could be designed with a more precise handle on the actual number of ADEs or clinical signs as the numerator divided by the total number of doses administered as the denominator. The resulting number would give a better estimate of incidence, but this could also be very expensive.

The length of time that a product has been on the market is also a factor. Generally ADEs for products that have been on the market for over 2 years are underreported. Pharmaceutical companies, veterinarians, and consumers become complacent about reporting ADEs on products that have been in use for many years. Veterinarians may be especially reluctant to report ADEs on well-known products that have been marketed for several years with few instances of side effects.

Report quality is a problem because veterinarians, lay staff at veterinary hospitals, and consumers do not always report all of the information (e.g., laboratory tests, concomitant drugs and preexisting medical conditions). Economics may be a factor because of some clients' reluctance to spend money on laboratory tests. Veterinarians simply may not want to take the extra time to evaluate and communicate laboratory results to the sponsor.

Regulatory Actions

The ADE database contains several thousand reports from 1987 to the present consisting of companion and food animal species. Safety reviewers manually enter relevant medical data such as the suspect drug, species, breed, weight, age, sex, and clinical signs into the database. At the same time, safety reviewers evaluate the clinical signs in the ADE report using the modified Kramer algorithm.

Presently safety reviewers identify trends and alert the product manager. Safety reviewers are veterinarians who are trained to evaluate ADE data and recognize trends. Product managers are veterinarians who are assigned to monitor the safety and effectiveness of specific products.

A group of similar clinical signs submitted in several ADE reports in a short period of time may be interpreted as a signal for further investigation by the CVM and the drug company. In the event that a potential problem is identified, the Monitored Adverse Reaction Committee (MARC) is convened by the product manager and the ADE coordinator to assist in evaluating information related to the potential problem. The MARC consists of experts from throughout the CVM to include the Office of New Animal Drug Evaluation (ONADE), the Office of Research (OR), and the Office of Surveillance and Compliance (OSC). There is a standing invitation for ONADE experts from the Divisions of Manufacturing and Chemistry, Food Animals, Companion Animals, or Human Food Safety, depending on the particular drug and needs of the MARC. Scientists from the OR are invited on an ad hoc basis. In the OSC product managers and ADE safety reviewers from the Division of Surveillance serve as the lead in presenting ADE data for review by the MARC. Subsequently the MARC recommends appropriate regulatory action if the problem is considered significant. This investigation may result in product recall of the affected lot(s) or a label change. The label change includes new information from the ADE reports containing clinical signs with a positive causality assessment. "Dear Doctor" letters are often issued by the company in conjunction with label changes at the request of the CVM. The "Dear Doctor" letters inform veterinarians about the label changes or other actions taken by the CVM and the industry. On rare occasions a drug may be removed from the market through voluntary recall by the company or withdrawal by FDA of the approval because the new evidence shows that the drug is no longer safe for its intended use. ADE information is released to the public by means of summary report publication on the CVM website. Additional requests for ADE information can be made through the Center's Freedom-of-Information Officer (HFV-12, 7519 Standish Place, Rockville, MD 20855, 240-276-9017).

Most Frequent Adverse Drug Reactions in Dogs and Cats

The thirty most frequent clinical signs in descending order for dogs and cats are summarized in Box 20-2. The clinical signs become adverse drug reactions when they receive positive causality assessment scores. For dogs the summarized list represents about 80,000 adverse reactions out of about 100,000 exposures across all animal drugs in the database during the period 1987 to the present. For cats the summarized list represents about 19,000 adverse reactions out of about 33,000 exposures across all animal drugs in the database during the period 1987 to the present. Specific drugs can be found on the CVM website.

The three most frequent signs for dogs and cats are depression/lethargy, vomiting, and anorexia. Overall this may be an accurate reflection of the entire population of dogs and cats in the United States, but it is mainly to the result of clinical signs that can be readily visualized by veterinarians versus specific laboratory results in the ADE database. Similarly, pet owners tend to report only clinical signs that are easily observed. This is to be expected because consumers usually do not report the results of

*Only about 10% of some ADEs or clinical signs are reported.

Box 20-2

The 30 Most Frequent Adverse Drug Reactions in Dogs and Cats*

Dogs	Cats
Vomiting	Depression/lethargy
Depression/lethargy	Vomiting
Anorexia	Anorexia
Ineffective for heartworm larvae	Death
High alkaline phosphatase	Application site alopecia
Diarrhea	Ataxia
High SGPT/ALT	Diarrhea
Death	High BUN
Convulsions	Mydriasis
Ataxia	High creatinine
High BUN	Fever
High total bilirubin	Ineffective anesthesia
Death (euthanized)	Convulsions
Anemia	Hypersalivation
High creatinine	Dyspnea
Anaphylaxis/anaphylactoid	Apnea
Fever	Blindness
Pruritus	Prolonged anesthesia recovery
High WBC	Trembling
Bloody diarrhea	Death (euthanized)
Polydipsia	Cardiac arrest
Trembling	Application site lesions
Weight loss	Pruritus
Low platelets	Ineffective for ear mites
High SGOT/AST	Alopecia
Icterus	Dehydration
Polypnea	Anemia
Drug interaction	Ineffective for fleas
Weakness	Vocalization
High liver enzymes	Weight loss

BUN, Blood urea nitrogen; SGOT/ALT, serum glutamic oxaloacetic transaminase/aspartate aminotransferase; SGPT/AST, serum glutamic pyruvic transaminase; WBC, white blood cell count.

*The thirty most frequent clinical signs with positive causality assessment scores are listed in descending order across all approved drugs in the CVM database during the period 1987 to the present.

laboratory results and necropsy reports to the company or the CVM. In addition, many owners are more reluctant to pay for laboratory tests than for the forensic tests that are done much more routinely in human medicine. Therefore it is imperative that the practitioner gather as much information as possible when reporting an ADE to the sponsor. Laboratory results can make a difference between establishing a stronger association between an ADE and the drug and not having enough information to make any determination. Conversely, laboratory tests can cause a clinical sign to be placed in the “Unlikely” category.

Benefits of ADE Reporting

Practitioners should be able to depend on the label information to make professional decisions about the risks and benefits of the associated drug. The purpose of pharmacovigilance is to give some assurance that the animal drug

labeling is accurate beyond the initial product launch. One ADE report does not provide enough information for a label change. A reliable safety profile emerges only after a product is marketed and administered to a relatively large population of animals. The pharmacovigilance network involves veterinarians, industry, and regulators. Practicing veterinarians play a pivotal role as observers and reporters of ADEs. Despite the scrutiny of drugs that undergo FDA approval, it is impossible to know everything about a drug before approval. Animal drug pharmacovigilance remains the best tool available to communicate risk to veterinarians and consumers in spite of the limitations of ADE reporting and evaluation.

GLOBAL PHARMACOVIGILANCE REPORTING

The U.S. Department of Agriculture and the FDA are participants in the construction of a global adverse event reporting platform. The reporting format for ADEs will be standardized; but the causality assessment, the evaluation of risk for each ADE, and the pharmacoepidemiologic approach that may include mathematic analyses will not be. Global harmonization of reporting requirements for ADEs is no small task. It must be kept in mind that, unlike human ADEs, veterinary medicine deals with multiple species, which adds more complexity to an already complicated process. In addition, reporting requirements differ substantially from country to country because missions, goals, resources, administrative procedures, and ADE sources vary considerably. The variations reflect the fundamental differences in the worldwide agencies and the laws they administer.

The International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH), is a trilateral organization (EU-Japan-USA) with two observer countries (Australia and Canada) whose aim is to harmonize technical requirements for animal medicinal product registration to include preapproval review and postapproval monitoring. In 1996, at the inception of VICH, one goal was the harmonization of pharmacovigilance reporting requirements: definitions, data elements, electronic submission protocols, and medical dictionaries.

Successful efforts of VICH will lead to the timely transmission of ADE information among all parties and organizations involved in animal pharmacovigilance. Electronic reporting standards will also be available to consumers and veterinarians who could report directly to the regulatory agency rather than the company. The standardized ADE information will be disseminated worldwide for examination and analysis by all interested parties.

CHAPTER 21

Sources of Help for Toxicosis

MICHAEL J. MURPHY, *St. Paul, Minnesota*

Practitioners faced with questions about toxicoses can access a number of resources. These include specialists in veterinary toxicology, veterinary diagnostic laboratories, colleges of veterinary medicine, textbooks, on-line references, and poison control centers.

Perhaps the best source of veterinary toxicology information comes from veterinarians certified by the American Board of Veterinary Toxicology (ABVT) as specialists. The ABVT is one of the most established specialty groups recognized by the American Veterinary Medical Association's Board of Veterinary Specialties. A listing of ABVT Diplomates is available at www.abvt.org. Consultation with an ABVT toxicologist can be particularly helpful in complicated or obscure cases of toxicosis.

Many veterinary diagnostic laboratories and Colleges of Veterinary Medicine (CVMs) include ABVT Diplomates on staff. The veterinary diagnostic laboratory accredited by the American Association of Veterinary Laboratory Diagnosticians nearest to your practice can be identified by checking accreditation at <http://www.aavld.org>; colleges of veterinary medicine can be found at [\[avma.org/education/cvea/colleges_accredited/colleges_accredited.asp\]\(http://avma.org/education/cvea/colleges_accredited/colleges_accredited.asp\).](http://www.</p>
</div>
<div data-bbox=)

Many practicing veterinarians have reference texts available in their clinic. Most veterinary toxicology texts are authored by ABVT Diplomates. A partial list of such reference texts that I recommend beyond this textbook includes the textbook series *A Field Guide to Common Animal Poisons*, by Murphy (www.blackwellprofessional.com); *Clinical Veterinary Toxicology* by Plumlee (Mosby, www.us.elsevierhealth.com/Veterinary); *Small Animal Toxicology* by Peterson and Talcott (Saunders, www.us.elsevierhealth.com/Veterinary); and *Toxicology* by Osweiler (Williams & Wilkins, www.lww.com).

Poison control centers are another leading source of toxicology information. Some centers specialize in animals. Even though most poison control centers specialize in human exposures, about 135,000 animal exposure calls were recorded by human centers in 2004. Animal poison control centers include the American Association for the Prevention of Cruelty to Animals Animal Poison Control Center (www.aspc.org/apcc), the Pet Poison Helpline (www.petpoisonhelpline.com), and human

poison control centers. Animal poison control centers may charge for services and information. The telephone number for the human poison control center in many areas is 1-800-Poison-1.

The practicing veterinarian should consider in advance the various sources available for information regarding animal toxicoses. Depending on the situation, a textbook reference or direct consultation with a toxicology specialist, veterinary diagnostic laboratory, college of veterinary medicine, or a poison control center may provide the information needed to appropriately manage toxicosis in the veterinary patient.

CHAPTER 22

Small Animal Poisoning: Additional Considerations Related to Legal Claims

MICHAEL J. MURPHY, *St. Paul, Minnesota*

"I think the neighbor is poisoning my pet."

Most practitioners hear this history many times in a career. Often the pertinent clinical signs are unrelated to any toxin; however, at other times toxicosis is the source of signs. Other chapters in this section are devoted to specific toxins or reporting of adverse events. This chapter considers situations when a pet toxicosis may involve the legal system.

Pet poisoning cases may involve the legal system through a variety of avenues, including insurance claims, product liability claims, civil claims, or criminal prosecution. As an example a criminal case is presented to highlight some of the issues that may arise when an animal toxicosis involves the legal system.

Celinski v. State

The criminal application of the Texas animal cruelty statute was reviewed in the case of *Celinski v. State*. Mr. Celinski was found guilty of cruelty to animals in part for poisoning two cats with acetaminophen. He appealed the conviction. The conviction was upheld by the Texas Court of Appeals based on the evidence.

The evidence cited by the Texas Court of Appeals in upholding Mr. Celinski's conviction was:

- "(1) The cats were in good health when Jones [the owner] left; they were very sick when she returned the following day. They had diarrhea, were foaming at the mouth, and were too weak to stand.
- (2) The veterinarian who treated the cats concluded that they were suffering from acetaminophen poisoning, based upon his observation of their physical symptoms and upon the results of a blood test.
- (3) The veterinarian was unable to reverse the results of the poisoning with an antidote. He estimated that the cats had ingested the equivalent of five to six tablets apiece some time during the afternoon of February 21, 1994.
- (4) Texas A&M laboratory results confirmed that Sugar Ray and Bonnie died of acetaminophen poisoning.
- (5) The veterinarian had seen a dozen cases of feline acetaminophen poisoning in his 14 years of practice, but had never heard of a cat voluntarily ingesting Tylenol, nor had he ever seen a case of multiple cats simultaneously ingesting Tylenol.
- (6) Appellant testified there were no pills lying about the apartment the day the cats became sick—pills they could have accidentally ingested. He was the only person present in the apartment with the cats on that day." (*Celinski v. State*)

NOTE: Criminal cases are commonly cited as *State v. Doe*, since the state is prosecutor and the individual accused of doing the poisoning is the defendant in the initial trial. In this case, Mr. Celinski appealed the initial court ruling to the Texas court of appeals; thus the case is *Celinski v. State*.

Other Signs

Mr. Celinski was also convicted of putting the cats in the microwave and turning it on. The cats had blistered feet, and some of their other signs could be related to the microwave.

The interest of the legal and medical professions is generally quite similar in these cases. That interest is to determine whether exposure to the suspect chemical caused the disease present in the animal. Both professions gather and analyze facts to determine whether such a conclusion can be reached.

This case illustrates a number of points regarding the importance of medical records in legal cases. The first four points listed by the Court of Appeals may be used to determine whether the cats had a previous illness, whether they were exposed to a potentially toxic dose of acetaminophen, and whether the previously known adverse effects of acetaminophen were observed in the cats. The last two points reviewed by the court of appeals were more directly aimed at determining whether the exposure was accidental or intentional.

The first point noted by the Court of Appeals was that the cats were previously healthy and then became acutely ill. A *preexisting medical condition* that could explain the clinical signs or other adverse effects observed in the animal is likely to be considered in a legal setting. This analysis would consider whether the clinical signs of the animal could be caused by the preexisting condition, exposure to the purported toxin, or both.

The second point noted by the Texas Court of Appeals was the cats were exposed to a dose of acetaminophen known to be toxic. Acetaminophen was detected in the cats, confirming exposure. Analytic chemistry confirmation of the presence of the chemical in the animal is very useful in a legal setting to confirm that the chemical was actually absorbed into the animal. Analysis of blood and urine is most commonly used to support an argument of systemic exposure to the chemical. All of this information presumably assisted the veterinarian in estimating that the cats had received five to six acetaminophen-containing tablets apiece.

The fourth point noted by the Court of Appeals was the cats died of acetaminophen poisoning. The "physical symptoms" observed by the veterinarian included "dark chocolate color of a blood sample." This blood color led the veterinarian to suspect acetaminophen toxicosis. Acetaminophen was confirmed as the cause of death by the laboratory at Texas A&M University. A thorough necropsy with appropriate supportive testing also can be very useful both to rule in the suspect toxin and rule out other possible causes of the animal's clinical condition.

The veterinarian's medical record is likely to be an important source of facts in a legal case. Consequently,

the more facts present in the medical record, the stronger the support for an argument that the suspect chemical, and not another etiology, caused the disease.

The last two points (5 and 6) were used to find that death from acetaminophen was intentional and not accidental. The distinction between accidental and intentional poisoning is important in animal cruelty statutes as discussed in the following paragraphs.

This criminal case raises important questions that may be considered in other toxicosis cases, specifically:

- What should be included in veterinary medical records?
- When is animal poisoning considered animal cruelty?
- Are drugs of abuse considered poisons?
- How is client confidentiality balanced with reporting animal poisoning?

What Should Be Included in Medical Records?

The veterinarian's medical records will likely be thoroughly reviewed if a medical case becomes a legal case. The pet's medical record may be broader than sometimes appreciated. For example, "registration forms, consent forms, radiographs, estimate sheets, billing records, telephone consultations, controlled drug logs, laboratory results, surgery reports, discharge records, imaging recordings, patient history, treatment records, and consultation reports" may all be considered a part of a pet's medical record (Scott, 2006). Specific suggestions of facts to include in the medical record when animal cruelty is suspected are:

"[w]henver nonaccidental injury is suspected, the attending veterinarian should obtain a minimum database, including estimated age, an accurate body weight, and a body condition score, and should perform a complete physical examination, a thorough oral examination to establish the condition of the teeth, otoscopic and ophthalmic examinations to identify potential head trauma, radiographic examinations to rule out occult injuries, and other species-specific examinations as necessary" (Babcock and Neihsl, 2006).

Despite these suggestions, the requirements for a veterinary medical record may be defined by the state in which one practices. This requirement, if it exists, should be considered. For example, the Minnesota Board of Veterinary Medicine has established, by Rule, the minimum standards for medical records for veterinary practice in Minnesota. Some of these record keeping requirements are:

"A. A veterinarian performing treatment or surgery on an animal or group of animals, whether in the veterinarians' custody at an animal treatment facility or remaining on the owner's or caretaker's premises, shall prepare a written record or computer record concerning the animals containing, at a minimum, the following information:

- (1) name, address, and telephone number of owner;
- (2) identity of the animals, including age, sex, and breed;
- (3) dates of examination, treatment, and surgery;
- (4) brief history of the condition of each animal, herd, or flock;
- (5) examination findings;

- (6) laboratory and radiographic reports;
- (7) tentative diagnosis;
- (8) treatment plan; and
- (9) medication and treatment, including amount and frequency."

Minnesota Rule 9100.800 sub. 4, A

Practitioners may choose to consult their state licensing board to determine if guidelines exist in that state for minimal data to include in veterinary medical records. One should consider including more than the minimal requirement if litigation is anticipated. Information to consider documenting in the record of suspected poisoning cases includes telephone consultations, laboratory test results, and consultation reports. Referral or consultation may not be required.

The increase in the number of veterinary specialty practices has raised the question of when a practitioner has a "duty to refer" a case (Rollin, 2006; Block and Toss, 2006). I am aware of no such obligation in pet poisoning cases. Rather the timely treatment of an animal that has been poisoned may argue against such a referral.

I also am not aware of a "duty to consult" on poisoning cases. However, such consultation may be wise in some cases. Several sources of information for poisoning cases are summarized in Chapter 21. The practitioner may consider consulting a veterinary toxicologist (www.abvt.org), a veterinary diagnostic laboratory (www.aavld.org), or both to receive advice on which samples and what testing may be desirable to confirm a suspected toxicosis to the "reasonable degree of medical certainty" normally required in a legal setting. Documenting in the medical record telephone consultations, including the results of specific toxin testing, the owner's decision to decline such testing, and any consultation reports obtained may strengthen the final diagnosis reached in a specific case. Notation of the rationale used to rule in the toxicosis and rule out other differential diagnoses also may be useful.

Sometimes the legal aspects of a case are unknown or not recognized at the time of patient presentation. Updating a medical record certainly can be proper. Subsequent reflection may suggest a need to update the record with the facts remembered but not initially recorded. However, the record should be amended only in a way that allows the original record to be read. "Entries that are completely blacked out or obliterated always raise suspicion when records are viewed by a third party.... The corrected entry should be signed and dated by the person making the correction" (Scott, 2006).

When is Animal Poisoning Considered Animal Cruelty?

Most toxic exposures in animals are accidental. Sometimes pets may ingest plants, pesticides, automotive products, and over-the-counter or prescription drugs available in or around the home despite the owner's best efforts to prevent them from doing so. Accidental adulteration of pet food has also occurred in the United States during the past several years.

These accidental exposures may require testing that specifically identifies the chemical causing the disease and rules out other reasonable etiologies whenever a claim against a property owner, pesticide applicator, product manufacturer, or other third party arises. The medi-

cal records and diagnostic considerations discussed in the previous paragraphs apply to these cases as well.

Rarely, animals are intentionally poisoned. In some states this element of intent may support an argument that a crime of animal cruelty has been committed. Animal cruelty statutes that include a version of the term "poison" are found in Arkansas, California, Hawaii, Maine, Michigan, Minnesota, North Carolina, New Mexico, Nevada, Ohio, Pennsylvania, Texas, Utah, and Vermont at the time of this writing. (see list in references). Most of these statutes indicate that the act be "knowingly," "willfully," "intentionally," or "maliciously" committed.

Animal cruelty may be a misdemeanor or a felony. For example, in Minnesota:

"[a]ny person who unjustifiably administers any poisonous, or noxious drug or substance to any animal, or procures or permits it to be done, or unjustifiably exposes that drug or substance with intent that the drug be taken by any animal, whether the animal is the property of the person or another, is guilty of a gross misdemeanor" (Minnesota Statutes 2005, Chapter 343.27).

In the United States animal cruelty may rise to the level of a felony in 43 states (Babcock and Niehl, 2006). For example, in Texas a person may be found guilty of a state jail offense if the person intentionally or knowingly: ...

"(5) kills, seriously injures, or administers poison to an animal, other than cattle, horses, sheep, swine, or goats, belonging to another without legal authority or the owner's effective consent..." (Tex. Penal Code Ann. § 42.09).

Presumably most cases of accidental unintentional animal poisoning would not satisfy the "intent" requirement of animal cruelty statutes. Consequently most pet poisoning cases would not likely rise to the level of animal cruelty, even in states where poisoning is recognized as one form of animal cruelty. Veterinarians should consider checking with their state licensing board to know the law in their state.

Are Drugs of Abuse Considered Poisons?

Alcohol, marijuana, cocaine, or other human drugs of abuse occasionally are encountered by veterinarians in emergency clinics or practices. Animals may certainly experience adverse effects after exposure to alcohol or these drugs (see Chapter 32). Many practitioners may not equate alcohol with "poison" in the routine veterinary practice. The Maine animal cruelty statute includes the phrase "gives poison or alcohol to an animal," apparently distinguishing alcohol from poison.

Screening pet's urine can be done to detect drugs of abuse using over-the-counter kits (Box 22-1). The kits are often used as a practical way to indicate to a concerned pet owner that such drugs are not detected in the urine of their animal when the test gives a negative result. Any positive results should probably be confirmed by analytical chemistry testing since most human kits have not been validated for use in animal urine. See www.aavld.org for laboratories that may be able to perform such analytical chemistry testing. It may be wise to consult the state licensing board to determine if positive findings for

Box 22-1

Websites for At-Home Tests To Detect Drugs of Abuse

<http://uritoxmedicaltesting.com/hometestkits.html>;

<http://www.testmyteen.com/storefront/?AffiliateID=1277&ACC=1277>

alcohol or human drugs of abuse identified in the urine of pets requires reporting to anyone not the client.

Balancing Client Confidentiality With Reporting

The question of client confidentiality should be considered whenever one considers reporting an animal's condition to someone who is not the client. For poisoning cases confidentiality is generally not an issue if the person or entity responsible for poisoning the pet is not the client. Clients may certainly disclose their pet's medical records to others at their discretion. Diagnostic laboratory reports confirming toxicosis have often been used to initiate investigations by a sheriff or humane officer when warranted. Presumably routine accidental animal toxicoses do not require reporting under animal cruelty statutes in most states because they do not meet the "intent" element, as discussed previously.

Balancing client confidentiality with reporting may be more difficult if the veterinarian suspects that the animal was intentionally poisoned by the client. See *Requirements for Mandatory Reporting of Animal Cruelty* for an expanded discussion of this issue (Babcock, 2006). Briefly, some states have mandatory animal cruelty reporting requirements or immunity from liability if animal cruelty is reported. Specifically Arizona, California, Illinois, Kansas, Minnesota, Oregon, West Virginia, and Wisconsin have a law requiring the reporting of animal cruelty (Babcock, 2006). Arizona, California, Colorado, Georgia, Idaho, Illinois, Florida, Kansas, Maine, Maryland, Massachusetts, Michigan, Mississippi, New Hampshire, New York, Oregon, Rhode Island, South Carolina, Vermont, Virginia, and West Virginia offer some immunity from liability for reporting suspected animal cruelty (Babcock, 2006). Veterinarians should consult their state licensing board for guidance before concluding that animal poisoning is animal cruelty that requires reporting to entities other than the client.

Some practice acts include very strong client confidentiality components. For example, the Texas Practice Act states:

"Confidential relationship between the veterinarian and a client:

Except as provided in subsection (c) of this section, a veterinarian shall not disclose any information concerning the veterinarian's care for an animal except:

(A) on written or oral authorization or other form of waiver executed by the client; or

(B) on receipt by the veterinarian of an appropriate court order or subpoena.

(C) A veterinarian may, without authorization by the client, disclose information contained in a rabies certificate to a governmental entity only for purposes related to the protection of public health and safety." (Texas Board of Veterinary Medical Examiners Rule 573.27 See also Tex Atty Gen Op JM-656. 1987 WL 269439).

In summary, the veterinarian's medical records undergo close scrutiny when cases of pet toxicoses involve the legal system. These cases may involve insurance claims, civil or criminal action in your state. Veterinary medical records are most useful in each of these legal settings when the differential diagnoses is outlined and the results of examination, laboratory testing, consultation, and specific diagnosis are laboratory documented in the medical record.

It may be wise for veterinarians to consult their state licensing board to determine if (1) minimal standards for medical records exist in their state, (2) detection of alcohol or drugs of abuse in a pet requires reporting to anyone other than the client, (3) poisoning an animal could be considered animal cruelty, and (4) their state requires the reporting of animal cruelty.

Urban Legends of Toxicology: Facts and Fiction

FREDERICK W. OEHME, *Manhattan, Kansas*

WILLIAM R. HARE, *Beltsville, Maryland*

Tens of thousands of potentially toxic exposures are reported to United States animal poison control centers annually. Many of these exposures are not life threatening. Understanding the realistic significance of these exposures depends on knowledge of the animal species, the actual toxicity of the chemical to which the animal was exposed, and the circumstances surrounding the exposure.

All substances must be considered potentially toxic; but whether clinical toxicity occurs is simply a matter of the dose delivered to the most sensitive biologic receptor. Given the numerous chemical and biologic variables involved in any exposure instance, it is not surprising that not all exposures to toxic substances result in clinical toxicosis. The role of the clinician is to review the case-by-case circumstances and offer appropriate judgment and recommendations. Favorable outcomes depend on prompt veterinary action in cases of true hazardous exposure.

All too frequently, however, individuals with emotional concerns and limited chemical and medical knowledge become vocal in news and electronic media—AKA the Internet—in declaring toxicologic problems inappropriately. These are often blanket statements incriminating products or situations as being the absolute causes of animal illnesses and deaths. Once these statements become ingrained in the media and are circulated widely, they become “urban legends.” Such *urban legends* may be repeatedly presented to veterinary practitioners as inquiries, concerns, or even *facts*.

The truth is that almost all are exaggerations of potentially risky situations or misinterpretations of related information that are erroneously applied to everyday events or behaviors. It then becomes the responsibility of veterinarians to apply their knowledge and people skills to clarify the concerns and hopefully place the urban legend in its appropriate category.

Following are a selected number of statements of toxicosis exposure situations that have commonly been reported to veterinarians. In some cases the concerns are quite valid, whereas in others there is no evidence for significant toxic risk. Many are rumors spread through Internet communications. It almost goes without stating to be careful of Internet misinformation. As much as we all appreciate information, to quote former President Ronald Reagan, “Information is good information only if it can be verified.”

Consider how you would respond to the following statements. Are they true, false, or possible? Remember that often it depends on those variables that ultimately come together to affect the outcome of every chemical exposure!

- **Ingestion of Swiffer WetJets kills dogs by liver failure.**

False: This product contains water (80% to 90%), propylene glycol (1% to 4%), isopropyl alcohol (1% to 4%), and preservatives (0.1%). Propylene glycol is much less toxic than ethylene glycol found in antifreeze, and this concentration of propylene glycol should not be problematic. If there is a problem following ingestion, most likely a foreign body has been introduced, or it is the result of a preexisting condition.

- **Macadamia nuts produce muscle weakness in dogs.**

True: Weakness, depression, and vomiting usually occur 6 or more hours after ingestion of a moderate quantity. About 1 nut per kilogram of body weight is usually enough to induce adverse clinical signs. Weakness and depression gradually improve after 24 hours in dogs without significant preexisting medical conditions.

- **Ingestion of grapes and raisins may result in acute renal failure in dogs.**

True: Vomiting, polydipsia, and lethargy can occur 5 to 6 hours after ingestion, followed by anorexia, anuria, tremors, and diarrhea. One to two grapes per kilogram of body weight may be enough to induce adverse clinical signs. Significant ingestion warrants prompt decontamination (emesis) followed by oral dosing with activated charcoal. In addition, aggressive fluid therapy within 48 hours may prevent acute renal failure from developing. Interestingly, this syndrome has not been reported in cats and not in all dogs ingesting these products.

- **Ingestion of sugarless candy/gum containing xylitol is poisonous to dogs.**

True: Weakness, ataxia, and total collapse may occur 30 to 60 minutes following ingestion of significant amounts of sugarless candy, gum, or breath-mints. Xylitol promotes insulin release by the pancreas, which results in profound hypoglycemia. Absorption is rapid, and activated charcoal is not efficacious in most instances. Acute hypoglycemia is best treated with intravenous dextrose—an initial bolus followed by continuous intravenous drip, with blood glucose concentrations being monitored over the next 12 to 24 hours.

- **Ingestion of Easter lilies (*Lilium longiflorum*) is highly poisonous to cats.**

True: Vomiting, hypersalivation, depression, and anorexia usually occur within to 1 to 2 hours after ingestion, followed by anuria and severe renal failure 2 to 4 days later. All parts of the plant should be considered poisonous, and almost all species of *Lilium* should be considered toxic. Dogs only appear to be affected with gastrointestinal upset. The sooner treatment is begun, the better the prognosis.

- **Tea is a good poisoning antidote for cats and dogs.**

False: Tea may contain 300 to 1200mg/oz of caffeine, whereas semisweet chocolate contains 22 to 138mg/oz, making tea on average 5 to 10 times more toxic than chocolate. Tea does have other beneficial actions, but for cats and dogs the bad effects from the high caffeine usually outweigh any potential good.

- **Ingestion of pennies and other coins are of little hazard for household pets.**

False: United States' pennies minted since 1982 are copper coated, weigh 2.5g, and contain 97.5% zinc. Although the adverse clinical signs of zinc poisoning, characterized by severe gastroenteritis and marked intravascular hemolysis, may be delayed following the ingestion of pennies, significant lodging of pennies in the acid media of the stomach increases the risk of zinc poisoning. Coins of other value do not contain zinc but can serve as foreign bodies.

- **Ingestion of chocolate can poison cats and dogs.**

True: All chocolates contain the methylxanthines caffeine and theobromine, which are toxic. Unsweetened baking chocolate (40 and 390mg/oz) contains the most methylxanthines, and white chocolate (0.8 and 0.2mg/oz) has the least. Hyperactivity, polydipsia, vomiting, diuresis, diarrhea, restlessness, tachycardia, cardiac arrhythmia, and seizures usually occur in a progressive fashion beginning shortly after significant ingestions. Treatment should be directed at decontamination, control of anxiety and seizures, and the support of renal elimination through fluid diuresis.

- **Centipedes, if eaten by pets, can cause harm to the ingesting animal.**

True: All species of the order Scolopendromorpha (i.e., centipedes having 21 or 23 pairs of legs) are venomous and can inflict harm by their bites or because they have been ingested. These centipedes have a stinging apparatus connected to their first pair of legs. Little is really known of their venom; however, various proteins, endopeptidase and cardiotoxin (toxin-S), as well as the nonprotein constituents serotonin, histamine, lipids, and various polysaccharides have been identified. No fatalities have been reported; but ingestion can produce vomiting, anxiety, and an irregular heartbeat or may simply induce a mild digestive upset.

- **Pot-scrubbing sponges contain dangerous amounts of Agent Orange (2,4-D + 2,4,5-T).**

False: Packages of these commercially available sponges are moist inside because a liquid antimicrobial is included to ensure that no fungal growth develops. The antimicrobial agent is a nontoxic disinfectant and even has some perfume added. Now our hands will smell nice after "doing pots and pans." However, if the sponges

become grease filled and are ingested, they could lead to gastrointestinal obstruction. It is best to properly dispose of these products following their use.

- **Cocoa beans, coca hulls, cola, coffee, and tea leaves should all be considered emergency ingestions in dogs.**

True: All contain variable but potentially toxic concentrations of methylxanthines (caffeine, theobromine, and theophylline). Depending on the dose ingested, acute vomiting, excitement, cardiac irregularities, tremors, and seizures may result. Treatment includes early digestive tract evacuation plus activated charcoal/cathartics, diazepam for seizures, and lidocaine or atropine for life-threatening cardiac effects.

- **Febreze, the odor elimination product, is dangerous for household pets.**

False: Zinc chloride, present in the pre-1998 formulation, was removed, and the product is now sold as a pump spray rather than as an aerosol that could be hazardous for birds in confined spaces. Febreze contains water, alcohol, a corn-derived odor eliminator, and fragrance. Toxicity is not expected with routine use, even with exaggerated exposure.

- **Onions and garlic can be bad for dogs.**

True: Although *bad* is a relative term, too much acute or lesser-but-frequent dietary onion or garlic produces depression, rapid heart and respiratory rates, and pale mucous membranes. The anemia results from free radicals that cause Heinz bodies to be formed, damage to red blood cells, hemolysis, and methemoglobinemia. Effects persist for several days after exposure stops. Vitamin C and/or administration of other antioxidants may have therapeutic benefits.

- **Herbal products can harm cats and dogs.**

True: When left open and available, potpourri, garden herbs, cooking powders, perfumes, and various odorants and similar scent products are attractive to cats. The essential oils in such materials are irritants, which cause damage to sensitive respiratory cells, skin epithelium, and mucous membranes in general. Herbal supplements may also contain steroids, benzodiazepines, heavy metals, analgesics, nonsteroidal antiinflammatory drugs, caffeine, atropine, and other constituents that are hazardous to pets that ingest or contact them.

- **Resolve spot and stain carpet cleaner is lethal when ingested by dogs and cats.**

False: The formulation for this product contains soap, sodium bicarbonate, alcohols 1.5% (ethanol, 2-propanol, and carbinol), glycols 1% (propylene glycol, methyl ether), citrus/pine scent, and water. It is not a lethal formulation. It can cause temporary minor eye irritation and a mild gastrointestinal upset if ingested. It is best to keep all household products out of the reach of pets.

- **Ingestion of caterpillars and butterflies by cats and dogs can be harmful.**

True: Several types of hair, setae, or bristles cover the bodies of butterflies, moths, and their caterpillars. These hairs are irritants and sometimes are associated with venomous glands. No less than 200 varieties of these insects are known to be poisonous. Harm may result as a

dermatologic syndrome, an ophthalmic injury, or respiratory and digestive syndromes. Mild gastrointestinal upset appears to be the most common hazard.

- **Ingestion of poinsettia flowers or leaves can make cats and dogs sick.**

True: Native poinsettia (*Euphorbia pulcherrima*) belongs to the large *Euphorbia* genus of flowering plants. This genus may contain a milkylike sap that contains diterpenoid esters. These compounds can act as irritants. On the other hand, cats or dogs chewing or ingesting the cultivated ornamental poinsettia flower or leaves rarely exhibit more than mild gastrointestinal upset or simply drool from the plant's taste. Serious consequences are rarely seen. Treatment usually consists of washing away the sap with a drink of water or milk.

- **Parenteral administration of penicillin G procaine can cause spinal cord damage.**

False: Penicillin G procaine is an equimolar salt of procaine and penicillin G in sterile solution. Penicillin G is one of the safest parenteral antimicrobial drugs available for use in animals. It has been used successfully for over 50 years. However, there are always exceptions. A significant amount of penicillin G procaine injected directly into the spinal cord or even injected epidurally could cause spinal cord damage. Likewise, use of penicillin in animals known to be hypersensitive to penicillin is problematic. Use is contraindicated in guinea pigs and chinchillas, as well as in certain species of birds, snakes, turtles, and lizards.

- **Vitamins A and D have toxic potential for most animals.**

True: Excessive amounts of vitamin A promote bone lesions with potential development of exostoses, which in turn may cause pressure on spinal nerves, resulting in paresis or other nerve deficits. Excessive amounts of vitamin D lead to hypercalcemia and calcium deposition of soft tissues, resulting in gastrointestinal, cardiopulmonary, and renal pathophysiology.

- **Ingestion of lipstick by your cat or dog will result in lead poisoning.**

False: The formulation of lipstick and other cosmetics is closely regulated and does not include lead as a constituent. However, many of the paints used in arts and crafts still do contain potentially dangerous levels of heavy metals (including lead, barium, cadmium, and mercury). Red, yellow, orange, green, violet, vermillion, white, and black paints may contain toxic heavy-metal pigments and may also be potentially carcinogenic.

- **Ultra Clorox contains lye and therefore is potentially dangerous for your dog.**

False: Both ultra Clorox and regular Clorox bleach formulations contain 5.25% aqueous sodium hypochlorite but not sodium hydroxide (AKA lye). However, sodium hypochlorite is still corrosive and may cause harm from eye or skin contact, ingestion, or inhalation. It is often used as a good premise disinfectant, but it is best to keep it away from pets.

- **Ingestion of Greenies treats is enjoyable but not risk free for cats and dogs.**

True: Greenies are hard, green, molded bone-shaped treats that contain wheat gluten, glycerin, cellulose, and

other additives that are both enjoyable and nutritious for pets. Greenies are intended to be chewed before ingestion to help prevent oral odors, tartar buildup, and gingivitis. Unfortunately pets occasionally will swallow large pieces of these hard treats rather than chewing them into smaller pieces. Ingestion of large pieces of Greenies has the potential of creating an esophageal or intestinal obstruction and fails to accomplish the intended use.

- **DEET Mosquito repellent products are safe for use on cats and dogs.**

False: All DEET (N,N-diethyl-m-toluamide)-containing mosquito repellent products are potentially toxic to cats and dogs. Hypersalivation, vomiting, anxiety, tremors, ataxia, and seizures may occur within 6 hours following excessive exposure. Animals need to be decontaminated (dermal washing, oral-activated charcoal), their hydration monitored, and supportive therapy initiated as soon as possible following exposure. There is no antidote.

- **Ingestion of environmental mosquito larvicides containing *Bacillus thuringiensis israelensis* (Bti) is deadly to cats and dogs.**

False: All mosquito prevention products containing BTI for use around the home (e.g., floating donuts, granules, liquids, briquettes) are generally safe. They may potentially cause a gastrointestinal upset 3 to 6 hours following ingestion, and on rare occasions ingestion of floating donuts could result in formation of a gastrointestinal obstruction. However, they do help eliminate mosquito pests.

- **Anything and everything can be potentially toxic for a companion animal.**

True: DOSE ALONE MAKES ALL THE DIFFERENCE !

As may be seen from the previous examples of urban legends taken from various Internet sites, some have selected validity, some are clearly erroneous, and others are half-truths and depend on the circumstances of exposure. Veterinarians called on to respond to clients' concerns about such electronic postings or related neighborhood rumors must use their knowledge, experience, and common sense to provide appropriate, realistic, and professional clarifying information.

In some instances questions about the real toxicologic facts may develop, and other professional resources may be researched. Colleagues certified by the American Board of Veterinary Toxicologists are widely available and can be contacted at nearby universities or animal poison centers. Clarification of related chemical details and the expertise of veterinary toxicologists are usually no more than a telephone call or computer keyboard click away; once the networking has been initiated, keep the phone number or online address in a readily available and visible place. Misconceived or erroneous urban legends fade away slowly!

Toxicosis Treatments

KELLY HALL, *St. Paul, Minnesota*

Small animal cases presenting to veterinarians after known or suspected toxin exposure can be both challenging and rewarding. Unfortunately, important information, including the type of toxin, dose ingested, potential co-exposures, or the time frame in which the patient was exposed may not be readily available at the time of presentation. Consequently attention should be directed toward treating the patient rather than the toxin and to *primum non nocere* (first, do no harm). Many excellent resources are available to help veterinarians and owners deal with toxin exposure in pets, including SafetyCall International's Pet Poison Helpline (1-800-213-6680), the ASPCA Animal Poison Control Center (1-888-4ANI-HELP), emergency clinics, veterinary schools, veterinary diagnostic laboratories (www.aavld.org), and veterinarians who are board certified in emergency and critical care (ACVECCS) or toxicology (www.abvt.org), among others. This chapter considers decontamination, specific antidotes, and supportive or symptomatic care in small animal patients exposed to toxins and makes suggestions for stocking therapies indicated to treat these patients.

DECONTAMINATION

Exposure to poisonous substances may not always result in toxicity. Toxicity requires both exposure and the adverse effect associated with that toxin. Toxicity is avoided when animals are exposed to subtoxic doses of chemicals. Decontamination and treatment to reduce absorption are indicated when the dose of toxin exposure is unknown or greater than the amount expected to cause clinical signs. Exposures in small animals may include surface or skin, ocular, airway, and most commonly oral.

Surface Exposure

Surface exposure in animals primarily occurs on the skin or eyes. Patients with dermal toxin exposures such as dermal permethrin exposure in cats should be bathed with a mild detergent, rinsed thoroughly, then towel dried. Body temperature should be monitored closely to prevent overcooling with bathing or overheating with dryer use, particularly in patients showing clinical signs or those without a controlled airway. Ocular exposure requires irrigation for 10 to 20 minutes with appropriate saline or other eyewash solutions. Contact lens cleaning solutions should be avoided because they contain agents that can further irritate the eye. A thorough ocular examination (including fluorescein staining for the presence of corneal ulcers and Schirmer tear testing) should be performed

after irrigation to evaluate for corneal lesions. If present, these should be treated appropriately.

Oral Exposure

Because of the curious nature of animals (particularly dogs), most toxicities are caused by oral exposure. In these cases inducing vomiting is often useful or curative. When clinically appropriate, emesis can be induced within 2 to 3 hours of toxin ingestion or when the timeline is unknown (unless medically contraindicated). For example, if an owner returns home after longer than 3 hours to find evidence of toxin ingestion, he or she does not know if the toxin was ingested 3 hours earlier (at which point it may be too late to decontaminate via emesis induction) or 30 minutes before the owner's return. A small moist meal may be offered before inducing vomiting to increase the likelihood of the toxin being included in the vomitus. Emetics and dosages used in dogs and cats are listed in Table 24-1.

However, inducing vomiting is contraindicated in seven instances.

1. Species that do not vomit such as some pocket pets, rodents, and rabbits
2. In patients already vomiting (there is no added benefit of emesis induction)
3. Following ingestion of a corrosive agent (emesis induction may further damage the esophagus and oral mucosa during vomiting, potentially leading to esophageal perforation); NOTE: If the agent is corrosive (i.e., bleach, battery acid), administration of water or milk at ≈ 1 ml/kg orally may be used to help dilute the substance
4. In the patient with epilepsy following ingestion of a stimulant that may induce seizures or in an animal that is already seizing (aspiration hazard)
5. In the patient with cardiovascular disease (emesis induction may be contraindicated because of stimulation of vagal reflexes leading to hypotension, bradycardia, and even cardiac arrest)
6. The comatose or otherwise debilitated patient that may have a reduced gag reflex, predisposing to aspiration pneumonia.
7. When patients have undergone recent abdominal surgery (the increased abdominal pressure may compromise sutures/abdominal wall healing)

When clinically appropriate, activated charcoal (AC) at a dose of 1 to 3 g/kg may be administered after the last vomiting episode via elective eating, orogastric tube administration, or force feeding (if swallowing). A brief delay of 15 to 45 minutes after vomiting is useful to minimize the risk

Table 24-1

Emetics Used in Dogs and Cats

Emetic	Dose	Side Effects	Comment
3% Hydrogen peroxide	6.5 ml/kg (1 teaspoon/5 cc) Can repeat once after 10 minutes Max: 44 ml per animal (3 tbsps, 9 tsp) Anecdotal, not useful in cats	Severe esophagitis, pharyngitis, or gastritis, especially when overdosed	Readily available Owner can administer at home
Apomorphine	0.04 mg/kg IV or 0.25 mg/kg conjunctiva Reversal agent: naloxone 0.04 mg/kg IM, IV, or SC Use in cats is controversial	Excitement, restlessness, central nervous system or respiratory depression, bradycardia	
Xylazine	Cat: 0.44 mg/kg IM Dog: 1.1 mg/kg SQ or IM Reversal agent: Yohimbine 0.1 mg/kg IV* should be readily available to reverse effects if profound	Cardiovascular and respiratory depression, hypotension, respiratory arrest	
Syrup of ipecac	Cat: 2.2 ml/kg; dilute 50:50 in water Dog: 2.2 ml/kg (not more than 15 ml) Value questioned in human medicine	Increase in lacrimation, salivation, bronchial secretions, and rarely cardiotoxicity, arrhythmias, hypotension, or fatal myocarditis	Owner can administer at home Unpalatable: may need nasogastric or orogastric tube to deliver in cats

IM, Intramuscularly; IV, intravenously; SQ, subcutaneously.

of charcoal aspiration or charcoal vomiting. However, too long of a delay in administering AC may result in more toxin being absorbed in the small intestine. A benefit of using apomorphine for emesis induction is that the effects can be reversed once the subconjunctival sac is flushed (or reversed with naloxone). If hydrogen peroxide is used to induce vomiting, there is always a risk the dog may vomit up the AC that was just delivered. Repeating half of the initial AC dose every 4 to 8 hours is useful in patients that have ingested toxins that have enterohepatic recirculation such as marijuana, nonsteroidal antiinflammatory drugs, ivermectin, and bromethalin. Finally the use of AC should be avoided when caustic material has been ingested because AC may potentially mask the ability to endoscopically evaluate the esophagus and gastrointestinal tract for damage.

Cathartics are included in many AC formulations to decrease gastrointestinal transit time. Specific cathartics include sodium sulfate (1 g/kg of body weight) and mineral oil (2 to 10 ml for cats and 5 to 30 ml for dogs). Extreme caution should be used with administration of mineral oil because aspiration into the airways from vomiting or misplacement of the orogastric tube can have catastrophic consequences.

SPECIFIC ANTIDOTES

A small number of toxins have antidotes that are indicated when clinical signs of toxicity occur despite decontamination measures. An antidote is an agent that counteracts a poison and neutralizes its effects. Table 24-2 lists these antidotes, their indications, the appropriate dose, and recommendations for stocking in practice. Antidotes are discussed in the following paragraphs based on toxin.

Acetaminophen Toxicity

The combined use of *N*-acetylcysteine, cimetidine (Tagamet), and ascorbic acid is more effective in treating acetaminophen toxicity than any of the therapies used alone. Stocking *N*-acetylcysteine and *S*-adenosylmethionine (SAM-e) or having readily available access to a 24-hour pharmacy is suggested for veterinary practices because of the short period of time available for intervention in acetaminophen toxicosis. Cimetidine (intravenously) and ascorbic acid (oral or intramuscularly, as labeled) are over-the-counter medications that can be added to the therapy regimen as soon as accessible if not stocked.

N-Acetylcysteine increases the synthesis and availability of glutathione, which binds and inactivates hepatotoxic metabolites of acetaminophen. Cimetidine may slow metabolism of acetaminophen into toxic metabolites by inhibiting the p-450 system in the liver. Ascorbic acid (vitamin C) enhances reduction of methemoglobin back to hemoglobin. SAM-e may be useful based on recent evidence suggesting that administration within 1 hour of acetaminophen ingestion to cats at a dose of 180 mg every 12 hours for 3 days and then 90 mg every 12 hours for 11 days improves clinical outcome (Webb et al., 2003). SAM-e use in a dog with acetaminophen toxicity has also been reported at an initial dose of 40 mg/kg of body weight orally followed by 20 mg/kg of body weight orally every 24 hours for 7 days (Wallace et al., 2002).

Anticoagulant Rodenticide Toxicity

Active vitamin K₁ enables the liver to produce clotting factors II, VII, IX, and X when their production is inhibited

Table 24-2

Antidotes Used in Dogs and Cats

Toxin	Antidote	Dose*	Recommended Practice Holdings (General, Emergency or Both)
Acetaminophen	Acetylcysteine (e.g., Mucomyst)	140 mg/kg PO initially, then 70 mg/kg q4h PO for at least 3-5 more treatments	Both
	Cimetidine (e.g., Tagamet)	5-10 mg/kg q6-8h PO or IV	Emergency
	Ascorbic acid (vitamin C)	20-30 mg/kg q6h PO	Neither
	S-adenosylmethionine (SAM-e)	<10 kg: 200-225 mg q24h PO 10 kg: 20 mg/kg (minimum dose) q24h PO	Both
Anticoagulant rodenticides	Vitamin K ₁	2.5-5 mg/kg q24h PO, SC × 2-6 weeks (depends on specific anticoagulant) Oral absorption is more rapid (with a meal) than SC; intramuscular injection is contraindicated in coagulopathic animals	Injectable: both Oral: emergency
Cholinesterase inhibitors	Pralidoxime chloride (2-PAM) <i>Organophosphate toxicity only: DO NOT use in carbamate toxicity</i>	10-20 mg/kg q8-12h IV (slowly) or SQ for at least 36 h	Emergency
Organophosphate or carbamate toxicity	Atropine	0.1-0.5 mg/kg, ¼ given IV with the remainder given IM or SQ; administered as needed	Both
Ethylene glycol (antifreeze)	Ethanol 20%	Dog: 5.5 ml/kg q4h × 5 doses, then q6h × 4; dosed IV as CRI over 1 h Cat: 5 ml/kg q6h × 5, then q8h × 4; dosed IV as CRI over 1 h	Both
	Fomepizole (4-methylpyrazole)	Dog: 20 mg/kg initially, 15 mg/kg at 12 and 24 hr, 5 mg/kg at 36 hr IV Cat: 125 mg/kg initially, 31.25 mg/kg at 24, 48 and 72 h IV	Both
Metals	Calcium EDTA	25 mg/kg q6h for 2-5 days SQ (dilute with D ₅ W solution to 10 mg/ml)	Both
Lead, zinc, copper, iron	Meso-2,3 dimercaptosuccinic acid (DMSA, succimer)	10 mg/kg q8h for 5 days, then 10 mg/kg q12h for 2 weeks PO	Emergency
Iron	Deferoxamine	10 mg/kg q8h for 24 h IM or IV	Emergency
Metronidazole	Diazepam	Dog: 0.2-0.7 mg/kg initially IV, then q8h PO Cat: unknown (oral diazepam can be associated with hepatic necrosis in cats)	Both
Serotonin syndrome	Cyproheptadine	Dog: 1.1 mg/kg, q4-6 h PO Cat: 2-4 mg/cat, q4-6 h PO Can crush, dilute in saline, and give rectally; can administer until signs resolve	Emergency

*Dog and cat dose if not further specified.

CRI, Continuous-rate infusion; DMSA, dimercaptosuccinic acid (DMSA, succimer); D₅W, 5% dextrose in water; EDTA, ethylenediaminetetraacetic acid; IM, Intramuscularly; IV, intravenously; SQ, subcutaneously; NE, nasoesophageal; PO, orally.

by anticoagulant rodenticides. Vitamin K₁ therapy takes approximately 6 to 12 hours after oral or subcutaneous administration to clinically improve circulating clotting factor activity. It is best absorbed orally when given with a small fatty meal that stimulates bile salt secretion. Therapy needs to continue as long as anticoagulant rodenticide is in the body. This may be 2 to 4 weeks for the newer compounds. See Chapter 25 for more detail. Prothrombin time should be evaluated 48 to 72 hours after therapy

has ended to ensure appropriate efficacy of therapy. Oral dosing can be initiated in eating, asymptomatic patients; however, the subcutaneous injectable form may be necessary in patients symptomatic for blood loss associated with toxicity. Intramuscular injections are not recommended in animals with a coagulopathy or thrombocytopenia. Finally, intravenous vitamin K₁ can result in acute anaphylactoid reactions. The injectable form of vitamin K₁ should be available in all practices.

Cholinesterase Inhibitor Toxicity

Organophosphate and carbamate insecticides are termed cholinesterase inhibitors. These chemicals inhibit the cholinesterase enzyme and reduce the normal breakdown of acetylcholine. Acetylcholine is a transmitter for both the nicotinic and muscarinic systems. Clinical signs are associated with overstimulation of these pathways.

Pralidoxime chloride (2-PAM) may relieve the nicotinic signs of muscle fasciculation and the muscarinic signs of salivation, bronchospasm, lacrimation, urination, or defecation in cholinesterase inhibitor toxicosis. It is most effective when given within 24 hours of exposure; thus it should be stocked or otherwise readily available. A greater time delay between exposure and 2-PAM treatment allows for stronger binding of some organophosphates with the cholinesterase enzyme. This binding makes 2-PAM therapy ineffective. 2-PAM is not indicated in cases of carbamate carbaryl toxicosis because it also inhibits the cholinesterase enzyme to some degree.

Atropine is typically stocked in most practices for multiple purposes and can be used in cholinesterase inhibitor toxicity to assist with resolution of muscarinic signs. Glycopyrrolate can also be used but has a slower onset and a longer duration of action and can be used in lieu of atropine.

Ethylene Glycol (Antifreeze) Toxicity

Acute renal failure in ethylene glycol (EG) toxicity is caused by oxalate and other products formed by metabolism of the EG molecule. Fomepizole and ethanol competitively inhibit alcohol and aldehyde dehydrogenase to prevent formation of these nephrotoxic metabolites. Initiation of therapy within 6 to 8 hours in dogs and 2 to 3 hours in cats of EG exposure is paramount for a successful outcome. Consequently, one or both of these products should be stocked in all practices.

Fomepizole (4-methylpyrazole) used at high doses has been successful in cats if initiated within 3 hours of exposure (Connally, Thrall, and Hamar, 2002). Fomepizole is quite expensive, which may be a factor in stocking for some practices.

Ethanol (20% concentration) may be beneficial if adverse effects are appreciated. Addition of 250 ml of 100% ethanol (e.g., Everclear) to 1-L bag of crystalloid fluid creates a 20% solution. Although profound central nervous system depression and increased serum osmolality side effects can be observed, the time frame of therapy overrides these factors. Ethanol should still be given judiciously, with cessation if any of the clinical signs are observed: lateral nystagmus, respiratory depression, or if the patient becomes too obtunded.

Metals

Therapies for lead, zinc, iron, copper, and other metal toxicosis include chelating agents that “trap” the metal to form a water-soluble product that enhances urinary excretion. Deferoxamine is the most effective chelator

of iron. Deferoxamine therapy works best if administered within 12 hours of ingestion or exposure. Supportive care alone may not prevent mortality. Calcium ethylenediaminetetraacetic acid is a chelator useful in lead and zinc toxicity, although it is only available in injectable form. Meso-2,3 dimercaptosuccinic acid is another chelator useful in lead toxicosis. Lead should be removed from the gastrointestinal tract before initiating oral therapy to prevent chelation and enhancing lead absorption from the gastrointestinal tract. D-penicillamine can be effective for long-term oral therapy of lead toxicity.

Metronidazole Toxicity

Diazepam is useful for management of neurologic toxicity associated with dogs that are receiving metronidazole (especially at dosages greater than 30 mg of metronidazole per kilogram per day for 3 to 14 days). Evans and colleagues (2003) documented significantly decreased recovery times in metronidazole toxicity when patients were treated with diazepam and supportive care for 3 days versus supportive care alone. Immediate improvement (which may be mild) can be seen when intravenous diazepam (Valium) is given as a one-time dose. Because injectable valium is an important therapy for seizure activity, it is recommended for virtually all causes of seizures and should be stocked in all small animal practices.

Serotonin Syndrome Toxicity

Serotonin is a neurotransmitter that acts centrally as an excitatory inhibitor and peripherally to stimulate smooth muscle. Many medications affect the amount of serotonin present in the synaptic space; these include the monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, and tricyclic antidepressants. Serotonin syndrome is caused by excessive serotonin in the synaptic space and was originally defined in humans as a constellation of symptoms, including at least three of the following: myoclonus, mental aberration, agitation, hyperreflexia, tremors, diarrhea, ataxia, and hyperthermia.

Cyproheptadine is a nonselective serotonin antagonist. If a positive clinical response is noted, it can be repeated every 4 to 6 hours orally or crushed and dissolved in saline and administered rectally until resolution of signs.

GENERAL THERAPIES

There is no specific antidote for most toxins. Furthermore, many sick veterinary patients have undiagnosed disease, with toxin exposure considered on their rule-out list. Accordingly, supportive and symptomatic care is the cornerstone for therapy in many patients—with and without known toxin ingestion. Table 24-3 lists therapies that are useful to stock in any practice, particularly for supportive care of toxicity patients. Determination of which items to stock is accomplished by reviewing frequency of use, shelf life, and availability from suppliers and local hospitals.

Table 24-3

General Therapies Useful in Supportive and Symptomatic Treatment of Poisonings

Drug	Use
Acepromazine	Sedation, anxiolytic
Ammonium chloride	Urinary acidification
Atropine	Bradycardia
β -blockers	Tachycardia
Calcium gluconate	Hypocalcemia
Dextrose solution	Hypoglycemia, hyperkalemia
Diazepam	Sedation/anticonvulsant
Dobutamine	Blood pressure support
Dopamine	Renal perfusion, blood pressure support
Doxapram	Respiratory stimulant
Fluids (e.g., crystalloid and colloid)	Volume expansion, rehydration, etc.
Furosemide	Hypercalcemia, diuresis
Mannitol	Cerebral edema, anuric renal failure
Naloxone	Opioid reversal
Opioids	Sedation, pain relief
Oxygen	Hypoxemia, CNS disease, carbon monoxide toxicity
Pentobarbital	Heavy sedation, anticonvulsant
Phenobarbital	Heavy sedation, anticonvulsant
Potassium chloride	Hypokalemia
Propofol	Anesthesia, heavy sedation
Sodium bicarbonate	Metabolic acidosis, hyperkalemia
Sucralfate	Esophageal and gastrointestinal protectant

CNS, Central nervous system.

Rodenticide Toxicoses

MICHAEL J. MURPHY, *St. Paul, Minnesota*

Pesticides account for about 25% of toxin exposures in pets. Insecticides (see Chapter 26) and rodenticides are the majority of these pesticide exposures. The rodenticides most frequently encountered by dogs and cats are anticoagulant rodenticides, cholecalciferol, strychnine, zinc phosphide, and bromethalin. Cholecalciferol is discussed in Chapter 36. The key aspects of toxicosis associated with anticoagulant rodenticides, bromethalin, strychnine, and zinc phosphide follow.

ANTICOAGULANT RODENTICIDES

The anticoagulant rodenticides continue to be the pesticide most commonly inquired about by animal owners. These compounds (including warfarin, brodifacoum, bromadiolone, diphacene, and chlorophacinone) represent a substantial proportion of actual toxicoses treated in veterinary and emergency clinics. All anticoagulant rodenticides act by inhibiting the recycling of vitamin K₁ from vitamin K₁ epoxide reductase. This inhibition leads to a reduction in the active forms of clotting factors II, VII, IX, and X in circulation, with factor VII and the extrinsic pathway affected initially. The reduction in the active forms of these factors leads to prolonged clotting times. Prolonged clotting time is most commonly measured by activated clotting time (ACT), one-stage prothrombin time (PT), activated partial thromboplastin time (APTT), or a combination of these tests in the clinic. Prolongation of these times to 15% to 25% above the upper end of the normal range is commonly interpreted as a coagulopathy. Toxic doses of anticoagulant rodenticides induce a coagulopathy. The coagulopathy is not always apparent on clinical presentation and typically is delayed for a number of days following ingestion. The so-called *second-generation* anticoagulant rodenticides have a much longer duration of action when compared to warfarin. The toxic dose and LD₅₀ for various anticoagulant rodenticides in dogs and cats is quite variable. Data for specific compounds can be found in consultation with toxicologists.

Anticoagulant rodenticide toxicosis should be considered in dogs or cats with dyspnea or exercise intolerance related to intrathoracic or intrapulmonary hemorrhage. Intrapulmonary hemorrhage occurs commonly in anticoagulant rodenticide toxicosis. Large pleural effusions and marked intrapulmonary hemorrhage (seen as a coarse, alveolar lung pattern) may be evident on thoracic radiography. Prolonged bleeding from venipuncture sites may be observed. Hematomas, hematemesis, melena, hemoptysis, hematuria, and pallor of mucous membranes are other relatively common clinical signs observed in animals

with anticoagulant rodenticide toxicosis. Bleeding may occur in unusual locations such as the pericardial space or into the spinal cord. Of course, anticoagulant rodenticides represent just one cause of coagulopathies in dogs and cats (see Chapters 59 to 62), and other bleeding disorders must be considered.

Detection of the specific anticoagulant rodenticide in serum is the most definitive means of confirming exposure to an anticoagulant rodenticide in a live animal. Liver is the specimen of choice for a dead animal. This testing is now available in many veterinary diagnostic laboratories throughout the United States (see www.aavld.org).

Anticoagulant rodenticide-induced coagulopathies are commonly distinguished from other causes of coagulopathy in the clinic by a relatively rapid response to vitamin K₁ treatment. ACT, PT, and APTT are each dramatically shortened within 24 hours of initiating daily therapy with 2.5 to 5 mg/kg of vitamin K₁ administered orally or subcutaneously (but *not* intravenously or intramuscularly) with a small-gauge needle. Anaphylaxis can occur with parenteral administration of K₁ by any route. Failure to see an initial response may suggest that the coagulopathy is not caused by anticoagulant rodenticide exposure. *Oral* therapy is very effective; some clinicians divide the daily dose into two or three treatments and aim to enhance absorption of the vitamin by administration with a fatty meal.

In certain cases of recent ingestion (within 2 to 4 hours of presentation), general measures for treatment of toxicosis should be considered, including induction of emesis and administration of activated charcoal (see Chapter 24). Clotting tests are often normal in these cases so they should be monitored for at least 3 days. Vitamin K₁ treatment should be administered if the clotting time is prolonged.

A severe coagulopathy may call for more than simple vitamin K₁ treatment, and the clinician must appreciate that effects of vitamin K₁ are not immediate. Animals with a packed cell volume less than 15 or those demonstrating complications of anemia may need fresh whole blood immediately. Furthermore, vitamin K₁ alone may be insufficient when results of coagulation tests show rapidly progressing prolongation in clotting times. In these cases, administration of fresh or frozen plasma may be needed to provide clotting factors. Blood product therapy may be required for 12 to 36 hours after initiating vitamin K₁ therapy to allow time for the synthesis of new functional clotting factors. Thoracocentesis may be needed if there is significant dyspnea related to bleeding within the pleural space. Rest and oxygen are appropriate for intrapulmonary hemorrhage.

The dose and duration indicated for vitamin K₁ varies with the specific anticoagulant rodenticide responsible for the coagulopathy. Dosages of 1 to 2.5 mg/kg daily for 3 to 5 days were often effective in treating toxicoses caused by warfarin and other first-generation anticoagulant rodenticides. The second-generation compounds, including brodifacoum, diphacene, and chlorophacinone, now comprise the majority of the market share; thus many practices treat with vitamin K₁ at 2.5 to 5 mg/kg daily for 2 to 4 weeks, especially if the specific anticoagulant rodenticide is not identified with certainty. Tests of clotting function can be useful guides for the duration of therapy. The bioavailability of vitamin K₁ is greatest when given orally; thus this route is preferred unless contraindicated because of vomiting. Vitamin K₁ may be given subcutaneously but should not be given intramuscularly or intravenously because of the increased risk of massive hemorrhage or anaphylaxis, respectively. Vitamin K₃ therapy is contraindicated because it is not efficacious and may induce oxidative damage to red cells.

Clients should be educated to remove all anticoagulant rodenticide bait from the pet's environment. Unfortunately pets occasionally are reexposed to rodenticide bait following discharge from the clinic. The long-acting anticoagulant rodenticides may be present in the serum and liver of the pet for weeks following successful treatment and recovery. Accordingly some anticoagulant rodenticides may be detected by analytic chemistry techniques in animals with no demonstrable coagulopathy and consequently no toxicosis.

BROMETHALIN

Bromethalin is the active ingredient in rodenticide baits marked under the trade names Assault (Agrisel) and Terminator (Syngenta). This compound acts by uncoupling oxidative phosphorylation and leads to hyperexcitability in the acute phase of toxicosis followed by depression in the chronic phase. Muscle tremors, seizures, hind limb hyperreflexia, and death may be observed within approximately 10 hours after exposure to 5 mg/kg. These signs may progress to depression, recumbency, coma, and death. Clinical signs of toxicosis may persist for up to 12 days after exposure to 2.5 mg/kg of bromethalin.

With analysis of bait, stomach contents, or vomitus it is possible to confirm exposure to bromethalin in a veterinary patient. Analysis of tissues, including fat, may be used to confirm exposure at postmortem examination. Routine complete blood count, serum biochemistries, and urinalysis generally do not assist in the diagnosis of exposure to bromethalin.

No specific antidote exists. Aggressive charcoal therapy (see Chapter 24) is aimed at reducing absorption and possible enterohepatic circulation of bromethalin. Mannitol and glucocorticoids have been used to reduce cerebral fluid pressure, but they may not reliably reverse clinical signs.

STRYCHNINE

Strychnine distribution has been restricted in many areas of the United States. It has been replaced by zinc phosphide in many areas.

Nevertheless, strychnine toxicosis is seen occasionally in clinical practice. Strychnine inhibits the postsynaptic buffering effects of glycine on sensory stimulation of motor neurons and interneurons. Consequently strychnine-poisoned animals appear apprehensive, tense, and stiff within minutes to hours of exposure. Rectal temperature may be increased from muscular hyperactivity. Clinical signs progress to tonic extensor rigidity, especially after sensory stimulation by light, sound, or touch. Animals often die in opisthotonus because of paralysis of respiratory muscles.

Urine samples obtained from a live animal and stomach contents retrieved from a dead animal are the samples of choice for analytic confirmation of exposure to strychnine. Other toxins can result in musculoskeletal stimulation, including mycotoxins, nicotine (Chapter 30), insecticides (Chapter 26), and zinc phosphide (see next section). Tetanus and hypocalcemia are other considerations.

Therapy is centered on sedating the patient to prevent seizures. This allows time for strychnine metabolism. Pentobarbital (2 to 15 mg/kg intravenously for dogs), administered to effect, is the most often used sedative/anticonvulsant. Methocarbamol may be administered for muscle relaxation at doses of 55 to 220 mg/kg intravenously. One half of the dose can be given as a bolus, with the rest administered slowly to effect. Daily dose should not exceed 330 mg/kg. Although diazepam normally is the initial drug of choice for seizing animals, efficacy for strychnine-induced seizures is variable. Activated charcoal may be administered to reduce further absorption as long as precipitation of seizures is avoided. Stimulation should be avoided, and a quiet, darkened hospital kennel may be beneficial. The patient should be given good nursing care, with attention to clinical and vital signs, as well as rectal temperature. Other treatments may include intravenous fluids and urinary acidification (ammonium chloride) to assist with urinary excretion.

ZINC PHOSPHIDE

Zinc phosphide is used for rodent and mole control and marketed under an increasing number of trade names, including Bartlett Waxed Mouse-Bait, Burrow Oat Bait, Rodent Bait, Rodent Pellets, ZIP RTU Bait, ZP Rodent Bait, and ZP Tracking Powder. This compound is more and more prevalent since it has replaced strychnine in many areas of the United States.

Animals exposed to zinc phosphide have a rapid course of clinical signs. These can progress through anorexia, lethargy, dyspnea, vomiting (occasionally with hematemesis), ataxia, agitation, muscle tremors, weakness, recumbency, and death. Signs develop within minutes to hours of ingestion of a toxic dose of zinc phosphide. Detection of zinc phosphide in the vomitus of a live animal or stomach contents of a dead animal supports the animal's exposure to it. Unfortunately this compound is volatile; freezing contents in air-tight receptacles may enhance the likelihood of detection in an analytic laboratory.

There is no specific antidote for zinc phosphide. Treatment is mainly supportive. Methods aimed at

moving zinc phosphide from the stomach in known cases of ingestion, including emetics, can be used. Increasing gastric pH may be helpful by reducing phosgene liberation. Milk of magnesia has been used as a home remedy; in the hospital gastric lavage with 5% sodium bicarbonate (take care to prevent bloat) may be used. Diazepam or pentobarbital may be needed for excessive musculoskel-

etal activity or seizures. In addition to intravenous fluid therapy, liver-supportive agents may be considered.

CHAPTER 26

Insecticide Toxicoses

PATRICIA A. TALCOTT, *Pullman, Washington*

Insecticides used in the United States to which small animals may be exposed include the organophosphate and carbamate cholinesterase inhibitor insecticides, the pyrethrin and pyrethroid groups of insecticides, the triazapentadiene compound amitraz, botanical insecticides, and miscellaneous insecticides that do not fit in any of these aforementioned groups. Each of these groups is discussed in turn.

ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

Organophosphate and carbamate insecticide poisonings are still one of the most commonly encountered toxicoses in small animals because of their widespread use on animals, around the house, and in agriculture (Hansen, 1995a, p. 245; Bonagura, 2000, p. 231). These insecticides may be used on animals intentionally or accidentally. Many exposures are accidental, caused by either inappropriate use by the applicator or accidental access to the product by the pet because of inappropriate storage or disposal of these compounds. Many insecticide products are intended to be applied to the premises or other property, but some are components of pet products including shampoos, flea and tick collars, and insecticide dips.

These products are generally formulated with oily vehicles or solvents to increase contact time and enhance stability. Literally hundreds of formulations are marketed in the form of sprays, dips, shampoos, collars, foggers, or bombs. These marketed products are sometimes mixed with food items to intentionally or maliciously expose pets.

Hundreds of cholinesterase inhibitor insecticides are marketed in the United States. See Box 26-1 for a list of

some of the more commonly used chemicals. The toxicity of these chemicals varies widely. Unfortunately there are few well-established toxic or lethal doses for dogs or cats reported in the literature. Dermal or oral exposures are commonly encountered by dogs or cats. The inhalation route of exposure is more common in humans. Most of the organophosphate and carbamate insecticides are rapidly metabolized by hepatic enzymes; then both the parent compound and its metabolites are rapidly eliminated in the urine. However, a few lipophilic compounds have longer half-lives, giving them a greater potential to cause central nervous system effects.

Both the organophosphate and carbamate insecticides inhibit the acetylcholinesterase (AChE) and pseudocholinesterase enzymes. AChE is responsible for breaking down acetylcholine released at cholinergic sites. Thus animals poisoned with cholinesterase inhibitors often exhibit a mixture of clinical signs as a result of overstimulation of the nicotinic receptors of the somatic nervous system (skeletal muscle), sympathetic and parasympathetic preganglionic junctions, all parasympathetic postganglionic junctions (few sympathetic postganglionic junctions), and some neurons within the central nervous system.

The onset of clinical signs can vary between a few minutes to several hours, depending on the dose, the route of exposure, and the specific chemical involved. Commonly reported muscarinic signs include excessive salivation, anorexia, emesis, diarrhea, excessive lacrimation, miosis or mydriasis, dyspnea, excessive urination, and bradycardia or tachycardia. The mnemonics SLUD (i.e., salivation, lacrimation, urination, defecation) and DUMBELS (i.e., diarrhea, urination, miosis, bronchospasm, bradycardia, emesis, lacrimation, salivation) are often used in the classroom

Box 26-1

Examples of Insecticides**Cholinesterase Inhibitors****Organophosphates**

- Chlorpyrifos
- Coumaphos
- Cythioate
- Diazinon
- Dichlorvos
- Dimethoate
- Disulfoton
- Ethoprop
- Famphur
- Fenthion
- Malathion
- Mevinphos
- Parathion
- Phorate
- Phosmet
- Terbufos
- Tetrachlorvinphos

- Cypermethrin
- Deltamethrin
- Esfenvalerate
- Fenfluthrin
- Fenvalerate
- Flumethrin
- Fluvalinate
- Permethrin
- Phenothrin
- Pyrethrin
- Pyrethrum
- Resmethrin
- Sumethrin
- Tetramethrin
- Tralomethrin

Triazapentadiene Compounds

- Amitraz

Botanicals

- d-Limonene
- Linalool
- Melaleuca oil
- Pennyroyal oil
- Rotenone

Miscellaneous

- Fipronil
- Imidacloprid
- Lufenuron
- Methoprene
- Methoxychlor
- Nitenpyram
- Pyriproxifen
- DEET
- Avermectins

Carbamates

- Aldicarb
- Carbaryl
- Carbofuran
- Methiocarb
- Methomyl
- Oxamyl
- Propoxur

Pyrethrins, Pyrethroids

- Allethrin
- Bifenthrin
- Bioallethrin
- Cismethrin
- Cyfluthrin
- Cyhalothrin

as a device to remember these changes. Prominent nicotinic signs include ataxia, weakness, and muscle twitching. In acute high-dose oral exposures, seizures can occur within 10 to 20 minutes. It is important to note that not all signs are seen in every poisoning case. Death is generally the result of respiratory failure and tissue hypoxia caused by excessive respiratory secretions, bronchoconstriction, paralysis of the respiratory muscles, and direct depression of the respiratory center in the medulla. Cats appear to be particularly sensitive to chlorpyrifos; anorexia, muscle weakness, ataxia, and depression are the predominant features. Exposure to these more lipophilic compounds has been referred to as the intermediate syndrome; additional clinical features may include muscle tremors, abnormal mentation, and abnormal posturing with hyperesthesia.

A clinical diagnosis of organophosphate or carbamate poisoning relies heavily on observing compatible clinical signs and a history of known exposure. Inhibition of whole blood, plasma, serum, retinal, or brain cholinesterase activity (at least 25% to 50% of normal) suggests an exposure to these compounds and toxicosis if the clinical signs are compatible. Cholinesterase testing can still be

performed after the administration of atropine and may still be useful several days after pesticide exposure. Lack of inhibition cannot rule out exposure to carbamate compounds because of the reversibility of their binding to the cholinesterase enzyme. In addition, because of the acuteness in onset of signs and possible death and the lack of some compounds to readily traverse the blood-brain barrier, brain cholinesterase may be normal in the acutely poisoned patient. Lower red blood cell counts may also lower true AChE activity; this is one reason to check the packed cell volume before running the assay. Therefore cholinesterase testing should be regarded as a screening tool, and false negatives and positives may occur. Tissue analysis for the organophosphate or carbamate insecticide is primarily reserved for confirming an exposure following a postmortem examination. Stomach and intestinal contents, liver, kidney, fat, and skin (in cases of suspect dermal exposures) should be collected, individually bagged and labeled, and kept frozen during shipment to a laboratory.

Changes observed on a complete blood count, serum chemistry panel, and urinalyses are typically very non-specific and highly variable. Pancreatitis accompanied by significant elevations in amylase and lipase has been reported following exposures to certain organophosphate insecticides.

Treatment should be aimed at preventing further absorption through aggressive decontamination procedures and controlling the muscarinic and nicotinic clinical signs. Many dermal exposures lead to subsequent oral exposures, particularly in cats; thus multiple decontamination procedures may be needed. In the asymptomatic orally exposed patient, emetics such as 3% hydrogen peroxide [a dose of 1 ml/pound; do not exceed a total dose of 10 ml in the cat or 50 ml in the dog, regardless of body weight; this volume has been routinely exceeded in dogs, and I have observed few serious complications; it can be used shortly after feeding a small amount of food] or apomorphine are generally recommended. If emesis is contraindicated, a gastric lavage can be performed after inducing light anesthesia, followed by the placement of a cuffed endotracheal tube. Induction of emesis and gastric lavage should always be followed with the use of activated charcoal and a cathartic. Administration of multiple activated charcoal doses may be warranted; care should be taken to reduce the subsequent cathartic doses and monitor the patient for the rare occurrence of hypernatremia or hypermagnesemia. A mild detergent bath and thorough rinsing are recommended in cases of dermal exposure. In the topically exposed patients, particularly cats, exposure may be both dermal and oral because of excessive grooming. In these cases both dermal and oral decontamination procedures may be beneficial.

Atropine sulfate, 0.20 to 0.50 mg/kg (one fourth intravenously [IV], the remainder subcutaneously [SC] or intramuscularly [IM]; some individuals administer the entire dosage IV), is used to control the muscarinic signs (e.g., miosis, salivation, diarrhea, bradycardia, bronchoconstriction). The dosage selected should be just enough to provide adequate atropinization, and atropine may be repeated at half the initial dose if signs return. Hypersalivation is often the most useful clinical sign for

monitoring atropine therapy. Oxygen therapy with or without artificial respiration may be required until the patient is breathing normally on its own.

Seizures, muscle tremors, or agitation can be controlled with intravenous diazepam, methocarbamol, or phenobarbital. Pralidoxime chloride (2-PAM; 10 to 20 mg/kg IM or SC BID or TID) can help reduce muscle tremors resulting from nicotinic receptor stimulation by an organophosphate. A clinical effect should be observed within the first 3 to 4 days, and treatment should be continued as long as improvement is observed. 2-PAM has its best effect if administered within 24 hours of exposure; but some benefits may occur, particularly in cases involving large toxin exposures, if given within 36 to 48 hours. Rapid intravenous injection may cause tachycardia, muscle rigidity, transient neuromuscular blockage, and laryngospasm. The use of oximes in cases of carbamate poisonings is somewhat controversial (particularly since the carbamate binding is reversible); one should weigh the benefits and risks of its use in each case. It is impossible to tell based on clinical signs alone whether the exposure was caused by an organophosphate or a carbamate insecticide.

Diphenhydramine use is also controversial in the treatment of organophosphate and carbamate poisonings; I do not recommend it. One suggested dose of diphenhydramine in dogs is 2 to 4 mg/kg orally every 6 to 8 hours. However, there have been reports of excessive sedation or excitement and anorexia when used in dogs and cats.

Good supportive and nursing care, including intravenous fluid therapy, adequate nutritional management, and maintenance of normal body temperature and electrolyte balance, should also be considered in the acutely poisoned patient. Chlorpyrifos poisoning in cats requires special attention; these cats often show signs of ataxia, anorexia, depression, and muscle tremors for several days or weeks after initial exposure.

PYRETHRINS/PYRETHROIDS

Pyrethrins are organic esters extracted with fat solvents from flower heads of the pyrethrum plant, *Chrysanthemum cinerariifolium*. Pyrethroids are their synthetic cohorts that vary in both structure and potency. Pyrethroids generally are more toxic to insects and mammals and persist longer in the environment than pyrethrins (Hansen, 1995b; Bonagura, 2000, p. 233). A number of commonly used pyrethrin and pyrethroid chemicals are listed in Box 26-1. Many of these pesticide formulations are registered for topical use on dogs and cats for flea and tick control. Other formulations are marketed for household use, and still others can be used in agriculture. These products can be purchased through many readily available outlets and packaged as sprays, dips, shampoos, and spot-on formulations. The percentages of active ingredient can range from less than 1% to as much as 65% or greater; therefore it is crucial to read the label thoroughly when using them.

There are hundreds of pyrethrin- and pyrethroid-containing formulations, sometimes combined in mixtures along with insect growth regulators, insect repellents, and various synergists. Piperonyl butoxide is a common additive to pyrethrin products. Although it possesses limited insecticidal activity, it acts as a synergist to extend

the killing duration of the pyrethrin. The mode of synergistic activity is not conclusively known. Hypothesized mechanisms of the synergistic effect of piperonyl butoxide include (a) prolongation of the action of pyrethrins by preventing rapid oxidation; (b) formation of complexes with the pyrethrins that lead to higher insecticidal activity; or (c) delay of pyrethrin detoxification by the insect's tissue enzymes. A number of pyrethroid products also contain insect repellents.

N-octyl bicycloheptene dicarboximide, di-n-propyl isocinchomeronate, and butoxypolypropylene glycol are insect repellents that are often present in pyrethrin/pyrethroid-containing products at concentrations ranging from 0.34% to 15%. Toxicity of these mixtures may be attributed solely to the pyrethrins and pyrethroids or be caused by the combined effects of the insecticides plus the additives, synergists, and solvents.

Pyrethrins work by stimulating the insect's central nervous system. This action results in muscular excitation, convulsions, and paralysis. When dissolved in thin oils, pyrethrins readily penetrate through the hard, chitinous covering of the insect, and their insecticidal action is rapid. Both pyrethrins and pyrethroids affect nervous tissue in mammals by reversibly prolonging sodium conductance, producing increased depolarizing afterpotentials that result in repetitive nerve firing. Their toxicity to mammals is low and, when used according to label instructions, should not induce deleterious effects in mammals. Toxicoses in mammals can be observed when these products are ingested or where there is overzealous heavy topical application, particularly in cats and small dogs. Many poisonings in clinical practice are the result of products labeled "for use in dogs only" being used on cats. There are also many anecdotal instances in which cats exhibited adverse effects following topical exposure to appropriately applied formulations. Clinical signs are normally observed within minutes to a few hours after exposure.

Clinical signs usually include excessive salivation (as a result of oral sensory stimulation), muscle tremors, depression, ataxia, anorexia, and vomiting. Less commonly reported adverse effects include weakness, dyspnea, diarrhea, hyperthermia or hypothermia, hyperesthesia (ear flicking, paw shaking; repeated contractions of the superficial cutaneous muscles), and recumbency. Occasionally one can see a topical allergic reaction characterized by urticaria, pruritus, and alopecia at the site of application. Death is rarely reported but can occur, typically following severe, uncontrollable seizure activity.

A clinical diagnosis of pyrethroid poisoning most commonly heavily relies on obtaining a history of recent use and access to these products. The clinical signs closely mimic other poisonings (e.g., organophosphate and carbamate poisonings), and there are no specific clinicopathologic abnormalities routinely observed in affected animals. Laboratory methods for analyzing pyrethrin/pyrethroid residues are not routinely available but can be done to confirm exposure if necessary. Since clinical signs often mimic organophosphate or carbamate poisonings, assessing blood or brain cholinesterase is recommended to rule out these differentials. Cholinesterase activity will not be inhibited in cases of pyrethrin/pyrethroid poisonings, whereas it may be in organophosphate or carbamate exposures and poisonings.

There is no specific antidote for pyrethrin/pyrethroid poisonings. Consequently treatment should be aimed at decontaminating the animal to prevent further absorption and addressing the clinical presentation. Bathing the animal in warm soapy water followed by a thorough rinsing is recommended for topical exposures. Long-haired dogs and cats may require multiple bathings-dryings-brushings or clipping to remove residues from the hair.

Oral ingestions can be treated with emetics, activated charcoal, and cathartics and more aggressively with light sedation and gastric lavage. Muscle tremors can usually be controlled with diazepam (0.5 to 1 mg/kg IV or to effect) or methocarbamol (55 to 220 mg/kg IV); it should be administered half rapidly, not to exceed 2 ml/minute, and the rest to effect. Continuous monitoring of body temperature for hypothermia or hyperthermia is essential. Providing adequate hydration and electrolyte status is also important in achieving a positive outcome. The oral cavity can be rinsed to help control hypersalivation. The prognosis for the majority of pyrethrin/pyrethroid poisonings is excellent, with most animals recovering within 24 to 72 hours.

AMITRAZ

Amitraz is a formamidine pesticide that is present in some tick collars used on dogs. It is often present at a concentration of 9%. The collars are designed to kill ticks for 4 months. Toxicosis can occur in dogs that ingest a substantial portion of, or the entire, collar. The entire collar weighs 27.5 g, so each gram of collar contains approximately 90 mg of amitraz. However, the collar is a controlled-release device that releases amitraz in first-order kinetics over an effective period of more than 90 days. Therefore release is much higher when the collar is new than after it has been used for 4 months. Mitaban liquid concentrate contains 19.9% amitraz. It is used topically for the control and treatment of generalized demodicosis. Several different treatment protocols have been suggested, depending on the location and severity of the disease and the age of the affected animal. The use of amitraz is not recommended in lactating or pregnant animals or in animals that weigh less than 5 kg.

The lethal dose of amitraz is estimated to be about 100 mg/kg orally in dogs, although toxic doses as low as 10 to 20 mg/kg have been reported. Amitraz is well absorbed by the gastrointestinal tract. Clinical signs of toxicosis usually begin within 1 hour of ingestion, sometimes as early as 30 minutes.

Amitraz is a monoamine oxidase inhibitor, an α_2 -adrenergic agonist, and an inhibitor of prostaglandin synthesis. Ocular exposure to this compound can lead to mild irritation. The clinical signs can be severe but often transient and rarely fatal. Most clinical signs are associated with the α_2 -adrenergic properties of amitraz and include depression, sedation, ataxia, bradycardia, mydriasis, hypothermia, vomiting, polyuria, and gastrointestinal stasis or diarrhea. Other signs that have been reported include hyperthermia, gastric dilation, hypersalivation, dyspnea, anorexia, shock, tachycardia, urinary incontinence, disorientation, tremors, and coma (Duncan, 1993; Grossman, 1993; Hovda and McManus, 1993). Clinical

laboratory data often reveal a hyperglycemia. Most signs, whether in mild exposures or excessive exposures followed by aggressive treatment, usually last no longer than 24 to 48 hours.

Treatment is aimed at decontamination to prevent further absorption and reversal of the adrenergic agonist effects. In the asymptomatic patient emesis should be induced with 3% hydrogen peroxide or apomorphine. Administering a nonoily laxative such as activated charcoal with a cathartic is recommended as long as no diarrhea is present. An enema to evacuate the colon may be administered 12 to 18 hours after ingestion if diarrhea has not occurred or the laxative does not produce the desired effect. Abdominal radiography is recommended if a length of collar is the suspected source of the amitraz or if the depression/sedation is severe and prolonged. Retrieval of the collar or pieces of collar can be performed by endoscopy, gastrotomy, or enterotomy. Xylazine should be avoided because of the possibility of exacerbating hypotension. All surgical procedures and anesthesia protocols should be considered carefully because of the potential to exacerbate preexisting problems of gastric dilation or bradycardia. The probability of requiring these more invasive decontamination procedures is rare.

Since amitraz is not a cholinesterase inhibitor, atropine and 2-PAM are contraindicated in the treatment of amitraz poisoning. In moderately or severely affected patients who cannot be aroused, yohimbine or atipamezole (both α_2 -antagonists) may be administered at 0.1 mg/kg IV or 50 mcg/kg IM, respectively (Hsu, Lu, and Hembrough, 1986; Hugnet et al., 1996). Both compounds should reverse amitraz-induced changes within 20 to 30 minutes. Since the action of yohimbine is of short duration (half-life = 1.5 to 2 hours), it may need to be repeated until the dog's clinical condition improves significantly. Body temperature should be monitored following yohimbine use to avoid hyperthermia. Fluid therapy is also warranted in the bradycardic, dehydrated patient.

BOTANICAL OIL EXTRACTS

Various fragrant volatile oils that are currently marketed as having parasitocidal properties have been isolated from a number of plants. The most popular of these oils include d-limonene and linalool. These oils are sold as shampoos, sprays, and dips for flea and tick control on dogs and cats or for premise control. Some citrus oil extracts are also found in household cleaners. These oils are considered to be relatively nontoxic and are generally regarded as safe by the Food and Drug Administration. Both d-limonene and linalool are present in oils extracted from the skins of citrus fruits and are typically associated with poisonings in dogs and cats when used at excessive concentrations. Cats are more sensitive to developing clinical signs after exposures than dogs.

With normal use these compounds may cause temporary irritation to the eyes, skin, nose, throat, or respiratory tract. Adverse reaction to these compounds can occur following inhalation, dermal, or oral exposure. Clinical effects are often observed within 15 to 30 minutes after exposure. Typical signs after oral exposure include salivation, vomiting, diarrhea, and central nervous system

depression. Other signs reported with higher exposures include muscle tremors, hypothermia, hypotension, ataxia, and mydriasis. Ataxia, weakness, depression, and dermal irritation (e.g., scrotal, perianal) have been seen following topical applications. Seizures and death are rare and are presumed to be secondary to severe hypotension and hypothermia. There has been one report of erythema multiforme major and disseminated intravascular coagulation in a dog following a dermal application of a d-limonene-containing dip (Rosenbaum and Kerlin, 1995). An acute necrotizing dermatitis and subsequent septicemia was reported in a 2-year-old cat following application of a d-limonene-containing insecticidal shampoo (Lee, Budgin, and Mauldin, 2002). Other signs reported included lethargy, inappetence, vocalization, and abnormal aggressive behavior.

Treatment is aimed at decontamination, with supportive care based on the clinical signs. Repeated bathings with warm, soapy water followed by thorough rinsing are recommended following topical applications. Gastric lavage with activated charcoal and a cathartic is recommended following oral ingestions. Body temperature and blood pressure should be monitored to prevent hypotension and hypothermia. Diazepam has been used to control the muscle tremors, and fluid therapy is generally recommended to prevent dehydration. Most affected animals recover within 24 hours.

Pennyroyal oil has long been used as a flea repellent and is sold as a shampoo, powder, or the pure oil itself. Pennyroyal is an herb consisting mainly of leaves from two different plants, *Mentha pulegium* and *Hedeoma pulegioides*. The oil is derived from the leaves and flowering tops of these plants. Pulegone constitutes approximately 85% of the pennyroyal oil and is metabolized to the toxic metabolite menthofuran by the liver. Toxicoses have been described in both animals and humans following dermal application and oral ingestion. Clinical signs are associated primarily with gastrointestinal upset, liver failure, and severe neurologic injury. Clinical signs include lethargy, vomiting, diarrhea, hemoptysis, epistaxis, dyspnea, miosis or mydriasis, seizures, and death (Anderson et al., 1996). Massive hepatic necrosis has been reported in the dog following topical application of the oil (Sudekum et al., 1992).

Pennyroyal oil ingestion is treated by decontaminating the stomach by gastric lavage and activated charcoal. Emesis is generally not suggested because of the rapid absorption of pennyroyal oil, the risk for developing aspiration pneumonia, and the potential for rapid onset of central nervous system depression. Repeated bathing with a mild detergent followed by thorough rinsings is recommended following topical applications. N-acetylcysteine has been suggested in cases in which there is a high risk of inducing a toxicosis, starting with a loading dose of 140 mg/kg and following with 70 mg/kg every 4 hours. N-acetylcysteine therapy should be beneficial within the first few hours of poisoning and should continue for at least 24 to 48 hours. The use of cimetidine has also been recommended in the treatment of this poisoning; mice pretreated with the cytochrome P-450 inhibitor cimetidine exhibited less liver disease associated with intraperitoneal pulegone administration than

the controls (Sztajnkrzyer et al., 2003). Any additional therapy is supportive only and should be based on clinical signs; this may include the use of antiemetics and fluid therapy. Basic support for liver failure may include plasma transfusions, antibiotics, vitamin K₁, S-adenosylmethionine, vitamin E, and gastric protectants (sucralfate). A complete blood count, serum chemistry and coagulation profile, and urinalysis should be performed to monitor organ function.

Another essential oil, Melaleuca oil or tea tree oil, is obtained from the leaves of the Australian tea tree (*Melaleuca alternifolia*). Melaleuca oil products are sold in products to be used topically for skin infections, as insect repellents, as antipruritics, or as household cleaners. Melaleuca oil is known to contain as much as 60% terpenes; thus the clinical signs in poisoned patients strongly resemble those described for the essential oils d-limonene and linalool.

Toxicities with these products have been reported in cats, dogs, rats, and humans, after either oral ingestion or topical application. Most reports of poisoning in pets occur after misuse of high topical doses of the product. The lipophilic terpenes are readily and rapidly absorbed across the skin and mucosal lining of the gastrointestinal tract. Cats are thought to be more sensitive than dogs, and toxicities might be observed more frequently in this species because of their fastidious grooming habits.

The onset of clinical signs may occur within minutes to 8 hours after topical application. The time interval is highly dependent on dose and the extent of oral exposure following grooming behavior. The most common adverse signs include ataxia, incoordination, weakness, tremors, depression, hypothermia, and behavior abnormalities (Villar et al., 1994). Elevation in liver enzymes (alanine aminotransferase, aspartate aminotransferase) has been reported in cats following topical exposure (Bischoff and Guale, 1998).

Treatment is directed toward symptomatic and supportive care. Topical exposures warrant bathing with a mild detergent followed by a thorough rinsing. Long-haired pets may benefit from having their hair cut or trimmed. Activated charcoal and a cathartic can be administered in orally exposed pets. Monitoring basic life support measures and correcting any temperature, fluid, and electrolyte abnormalities may be indicated. Prognoses are generally favorable, and most affected animals recover over a 2- to 3-day interval.

MISCELLANEOUS INSECTICIDES (METHOPRENE, LUFENURON, FIPRONIL, IMIDACLOPRID, PYRIPROXIFEN, NITENPYRAM)

Many of the insecticides described in this section are used topically. When an adverse effect related to topical/oral exposure to these products is suspected, it is essential to read the label ingredients carefully. Many of the insecticides listed in the following paragraphs can occur as a single ingredient or in combination with other insecticides, mainly pyrethrins and pyrethroids. In addition, several adverse reactions reported such as salivation or skin irritation following dermal or oral exposures may be caused by the carriers present in the formulation. Typically these signs are mild and self-limiting.

Insect growth regulators are a relatively new category in the war against fleas and ticks. All act as analogs of juvenile growth hormones, thereby interrupting the normal growth patterns of the insect. Methoprene preferentially kills fleas and ticks in the larval stage by binding to and activating juvenile hormone receptors. It thereby prevents larvae from developing into adult fleas. Methoprene can be absorbed from the gastrointestinal tract, through the intact skin, or by inhalation. However, it is considered to be virtually nontoxic when ingested or inhaled and only slightly toxic after dermal absorption. Methoprene is not considered an eye or skin irritant.

Lufenuron, a benzoylphenyl urea, inhibits the synthesis, polymerization, and deposition of chitin in the eggs or exoskeleton of fleas. Lufenuron is highly lipophilic and readily accumulates in adipose tissue. Lufenuron has shown no synergistic or additive effects when combined with other insecticides. It has proven to be safe at recommended dosage regimens in puppies and kittens as young as 6 weeks of age, as well as lactating dogs and cats and their offspring. Various studies in dogs and cats using up to 10 times the normal dosage have shown no serious health effects over an exposure period of 1 to 9 months. No adverse effects were seen in cats orally exposed to up to 17 times the recommended dosage. A mild decrease in food consumption was reported in puppies exposed from 8 weeks to 10 months of age to 18 to 30 times the recommended dosage. However, the majority of studies have shown no significant adverse effects on food consumption, body weight, hematology, clinical chemistries, and urinalyses following excessive exposures. Few effects on fertility and reproduction have been reported. Administration of lufenuron to breeding male and female dogs at 90 times the recommended dosage of 10 mg/kg resulted in a reduced pregnancy rate compared to controls. Pups born to treated females exhibited nasal discharge, pulmonary congestion, diarrhea, dehydration, and sluggishness. It appears that lufenuron concentrates in the milk at a 60:1 milk:blood concentration ratio (Ciba-Geigy Corp.).

Lufenuron, 90 mg/kg, was administered to breeding cats before mating and through gestation and lactation. Kittens born to these cats exhibited no adverse effects on health, growth, and survival (Ciba-Geigy Corp., 1996; Shipstone and Mason, 1995). Plumb (2005) lists vomiting, lethargy, depression, urticaria, diarrhea, dyspnea, anorexia, and reddened skin as rare adverse effects.

Fipronil is a phenylpyrazole flea and tick adulticide currently marketed as a spray and topical liquid that boasts a wide margin of safety. It can be used on dogs, cats, puppies, or kittens greater than 8 weeks old. No adverse effects were noted in studies in which dogs or cats were fed five times the maximum dose. Fipronil acts on the γ -aminobutyric acid-mediated chloride channels of invertebrates, thereby interrupting nervous transmission and leading to rapid death of the fleas and ticks. Mammals reportedly have receptors inside the chloride channel that are shaped differently than the invertebrate receptors, and fipronil is not thought to be able to bind them for a long period of time. Following dermal application, it is not considered systemically active and is thought to be sequestered in the pet's sebaceous glands. Mild skin irritation may occur following topical applications of these products.

Imidacloprid is another topically used adulticide that reportedly binds specifically to postsynaptic nicotinic acetylcholine receptors of insects and both kills adult fleas and exhibits some larvicidal action. Toxicity testing of imidacloprid has shown no adverse effects when used at five times the maximum dosage in dogs and cats. A few reports of alopecia and erythema have been observed following dermal application. Theoretically poisoning could occur by the oral route if the dosage or concentration were excessive. The most common complaint following ingestion is excessive salivation that is self-limiting. There is no specific antidote, and all treatment should be based on observed clinical problems. Topically exposed pets should be bathed and rinsed; orally exposed patients should be decontaminated by either emesis or lavage, followed by the use of activated charcoal and a cathartic.

Pyriproxifen and nitenpyram are two of the relatively newer products that have entered the marketplace. Nitenpyram is a neonicotinoid derivative that binds and inhibits specific nicotinic acetylcholine receptors. It does not inhibit AChE activity. Pyriproxifen is an insect growth regulator used topically to control insects. No significant adverse effects have been reported with either of these products.

CHAPTER 27

Parasiticide Toxicoses: Avermectins

WILSON K. RUMBEIHA, *Lansing, Michigan*

Avermectins are a group of parasiticial drugs derived from soil *Streptomyces* microorganisms. Biochemically they belong to a group of compounds known as macrocyclic lactones and are related to milbemycins. These drugs are widely used for their parasiticial properties. Representative drugs include ivermectin (Heartgard), selamectin (Revolution), doramectin (Dectomax), eprinomectin (Eprinex), moxidectin (Proheart), milbemycin (Interceptor), and abamectin. In general these drugs have a substantial margin of safety in dogs and cats and are very active against a wide range of parasites, including nematodes and arthropods. Practically they are highly effective at very low doses such as micrograms per kilogram of body weight basis. These drugs are not active against trematodes or cestodes. As such, they

may be combined with other drugs that are active against cestodes and trematodes in some formulations. They are available for oral, topical, and parenteral formulations for use in different domesticated species and humans.

TOXICITY OF AVERMECTINS AND MILBEMYCINS

Because of their wide safety margin, avermectins and milbemycins are used safely in the majority of dogs and cats. However, some specific breeds of dogs are more sensitive to this group of drugs (i.e., collies, Australian shepherds, Shetland sheepdogs, Old English sheepdogs, German shepherds, long-haired whippets, and silken windhounds). Recent findings have determined that

these breeds possess a mutation in the multidrug resistance (MDR-1) gene. This gene regulates the synthesis of P-glycoprotein, a 170-kDa transmembrane protein, which plays a key role in regulating movement of xenobiotics across the blood-brain barrier and other tissues of the body. P-glycoprotein is responsible for extruding drugs and other xenobiotics from the brain across the blood-brain barrier. A mutation in the MDR-1 gene causes synthesis of a truncated P-glycoprotein molecule that is unable to perform this regulatory role. The result is that breeds of dogs with this mutation cannot efficiently extrude xenobiotics such as avermectins and milbemycins from brain tissue. Studies have demonstrated higher concentrations of ivermectin in brain tissues of dogs with the mutated MDR-1 gene than naïve control dogs that have normal functioning P-glycoprotein.

Collies as a breed have the highest prevalence of the MDR-1 mutation. Research from United States, Europe, and Japan indicates that 75% of all collies carry this genetic mutation and explains why avermectin toxicosis is more commonly observed in this breed. This statistic includes dogs that are either heterozygous carriers or homozygous for the mutant allele, making the animal sensitive. Note that collies not holding this mutation (i.e., homozygous for the normal allele) have the same sensitivity to avermectin and milbemycin toxicity as other normal breeds of dogs.

It is worth noting that some mixed breeds of dogs carry a single recessive gene mutation, making them heterozygous carriers. These dogs have sensitivity to avermectin toxicosis, which is between that of double recessive-sensitive mutants and naïve dogs with normal alleles.

Toxic Dose and Sources of Exposure

The monthly oral dose of ivermectin for prevention of heartworms in dogs and cats is 0.006 to 0.024 mg/kg (6 to 24 mcg/kg of body weight), respectively. The LD₅₀ of ivermectin in beagle dogs is 80 mg/kg body weight. Most dogs with a normal MDR-1 gene tolerate oral dosages as high as 2.5 mg/kg body weight before they start to exhibit toxicity to this drug. However, dogs with a double recessive MDR-1 gene can only tolerate up to 0.1 mg/kg (100 mcg/kg of body weight) of ivermectin. Sensitive collies tolerated doses of 28 to 35.5 mcg/kg of body weight over a period of 1 year when administered oral chewable formulations of ivermectin. The highest observed nontoxic dose in cats is 1.3 mg/kg of body weight. However, toxicity in cats has been reported after as low as 0.3 mg/kg of body weight subcutaneously. Toxicosis to moxidexin was observed in a collie that received a dose 30 times higher than the recommended dose of 0.003 mg/kg of body weight. Toxicosis to milbemycin has been observed in collies at doses that are 10 times higher than the recommended therapeutic dose of 0.5 mg/kg orally. In one study collie sensitivity to milbemycin oxime at 10 mg/kg of body weight was judged to be clinically equivalent to that of ivermectin at 120 mcg/kg of body weight. Selamectin is potentially toxic to sensitive collies at oral doses greater than 15 mg/kg of body weight. For the other avermectins, the minimum toxic doses in sensitive breeds of dogs are not well established.

Typically toxicosis to avermectins and milbemycins is observed in the more sensitive breeds of dogs when dosage errors occur at >5 to 10 times recommended doses, depending on a specific drug; when dogs are accidentally given formulations for large animals; or when they eat a large number of drug tablets.

Clinical Signs of Toxicosis

Following acute exposure, clinical signs are seen within a few hours. However, clinical signs may also become evident after several days of topical exposure. Typically clinical signs of avermectin and milbemycin toxicity are associated with depression of the central nervous system. The animals develop ataxia, weakness, and recumbency; if the dose is severe, coma is evident. Some dogs exhibit signs of blindness and muscle tremors; in some cases seizures have been reported. These clinical signs result from avermectins acting as agonists of the γ -aminobutyric acid (GABA) in the central nervous system. Other non-GABA-related effects include mydriasis, hypothermia, vomiting, salivation, and shallow breathing. Avermectin toxicosis is a protracted disease that may last *days or weeks*. Treatment should be given with this in mind.

DIAGNOSIS AND THERAPY OF TOXICOSIS

Diagnosis of avermectin toxicosis consists of a history consistent with exposure to large amounts of these drugs, clinical signs consistent with avermectin intoxication, and chemical analysis of serum or blood plasma in live animals. In deceased animals adipose tissue, brain, and liver have been used for chemical analysis to confirm exposure to avermectins. However, there are no well-established concentrations of avermectins in these matrices that can be regarded as "diagnostic marker concentrations." As such, history of excessive exposure and clinical signs consistent with avermectin toxicosis remain the two most important diagnostic criteria to date. There is a molecular genetics test for the presence of a mutant gene (it is available at Washington State University Veterinary Clinical Pharmacology Laboratory). This test, which uses cheek brush samples, is helpful in determining whether an individual dog is sensitive to avermectins and other drugs with toxicokinetics that are regulated by the MDR-1 gene.

Therapy of avermectin toxicosis is symptomatic with no specific antidote. As such, prevention of absorption resulting from topical or oral exposure is key to successful therapy in cases of acute exposure. Animals exposed topically should be washed with mild dishwashing detergents and plenty of water. In cases of acute oral exposure, patients should be induced to vomit if exposure is within 1 to 2 hours. Apomorphine is recommended in dogs, and xylazine in cats as emetic drugs (see Chapter 24). Following emesis, activated charcoal can be given to bind the unexpelled drug. Avermectins are excreted largely unchanged through the feces. Activated charcoal may also be beneficial in binding these compounds that are normally excreted unmetabolized through bile and feces. Treatments with physostigmine, neostigmine, or picrotoxin have resulted in either temporary relief or mixed results.

Thus supportive care that includes fluid therapy, respiratory support, parenteral alimentation, and maintenance of normal body temperature is vital to a successful treatment outcome. Treatment of ivermectin toxicosis is likely to be protracted since these drugs have prolonged half-lives in dogs of at least 2 days for ivermectin, 11 days for selamectin, and 19 days for moxidectin. The effective half-life is likely longer in MDR-1 double recessive dogs, which are more likely to accumulate higher brain tissue concentrations.

CHAPTER 28

Lead Toxicosis in Small Animals

SHARON M. GWALTNEY-BRANT, *Urbana, Illinois*

Lead contamination of residential environments has decreased through removal of lead from residential paints, gasoline, and other household items. Accordingly, the incidence of lead poisoning in small animals has decreased over the last 30 years, and lead now accounts for less than 1% of reported accidental poisonings in pets. Nevertheless, lead intoxication in pets does occur, and the vagueness of clinical signs that frequently accompany lead poisoning can create diagnostic challenges.

SOURCES OF LEAD TOXICOSIS

Lead may be found in a wide variety of man-made products, including paints, linoleum, caulking and putty compounds, solders, wire shielding, old metal tubing, certain weights (e.g., fishing sinkers, curtain weights), linoleum, roofing felt, golf balls, ammunition, computer equipment, wine cork covers, pottery glazing, lead-containing toys, and lead arsenate pesticides. In addition, contamination of soil or water can be a potential source of lead. The potential for exposure to organoleads from leaded

petroleum products has decreased considerably following legislation restricting the use of leaded gasoline and oil in the United States.

The most common source of lead in cases of small animal poisoning is leaded paints from buildings built before passage of the 1977 legislation requiring that residential paints contain no more than 0.06% (600 ppm) lead. In many cases older leaded paints have been painted over with unleaded paints, and it is estimated that 74% of privately owned homes built before 1980 still contain hazardous amounts of leaded paint. Renovation of these homes results in the generation of paint chips or dust that, if ingested by pets, can result in clinical lead intoxication. Cats may be at increased risk for toxicosis during these situations because of their grooming habits, which can result in significant ingestion of lead-containing particulates that collect in their fur.

Kinetics

The degree to which ingested lead will be absorbed depends on variables such as the physical form of lead,

particle size, and matrix association. In addition, patient variables that influence the degree of lead absorption from the gastrointestinal (GI) tract include age, diet, and preexisting disease. The acidic environment of the stomach favors ionization of the lead, which is then absorbed from the duodenum. Lead shot embedded in soft tissues such as skeletal muscle is not appreciably absorbed and is not an important source of lead toxicosis. Conversely, lead shot that enters areas capable of active inflammation (e.g., joint cavities) may become solubilized by the enzymatic activity of the inflammatory reaction and could subsequently be absorbed.

Once absorbed, lead is carried primarily on the red blood cells, with less than 1% to 2% bound to albumin or free in the plasma. Unbound lead distributes widely through tissues, with the highest concentrations found in bone, teeth, liver, lung, kidney, brain, and spleen. Bone serves as a storage depot for lead, which substitutes for calcium in the bone matrix. During times of increased activity of bone remodeling such as fracture repair or lactation, stored lead may be released from the bone, resulting in toxicosis. Lead crosses the blood-brain barrier and concentrates in the gray matter of the brain. This passage of lead into the brain occurs to a greater extent in the young than in mature animals. Unbound lead crosses the placenta and is passed through the milk in lactating animals.

Most ingested lead is excreted in the feces unabsorbed. Lead in the blood passes through the glomerulus and accumulates in the renal tubular epithelium. During the natural process of sloughing of tubular epithelial cells, the lead is slowly eliminated from the body. Chelation therapy can greatly increase the rate of urinary excretion of lead by allowing the chelated lead to be passed in the urine without entering the tubular epithelium. Lead has a multiphasic half-life because of its distribution into depot areas such as bone and brain. In dogs intravenously administered lead has triphasic half-lives of 12 days, 184 days, and 4591 days.

Mechanism of Action

Lead has a wide variety of effects within the body, including interfering and competing with calcium ions, binding to cellular and enzymatic sulfhydryl groups, altering vitamin D metabolism, and inhibiting membrane-associated enzymes. Inactivation of the enzymes ferrochelatase and δ -aminolevulinic acid dehydratase results in impairment in heme synthesis, causing red blood cell abnormalities and, chronically, anemia. GI signs in lead-intoxicated patients may be caused in part by alteration of smooth muscle contractility as a result of interference of lead on intracellular calcium-dependent mechanisms. Lead decreases cerebral blood flow and alters neuronal energy metabolism and neurotransmission within the central nervous system (CNS).

Lead Toxicity

Toxic dosages of lead reported for dogs range from 191 to 1000 mg/kg, depending on the form of lead; 3 mg/kg/day caused vomiting and behavioral changes in cats. However,

these dosages have little clinical relevance in most cases of lead toxicosis in small animals since the amount of lead ingested is rarely determined.

Young animals are at greater risk than mature animals because they absorb up to five times more lead following ingestion. Lead absorption is enhanced in animals deficient in calcium, zinc, iron, and/or vitamin D. Younger cats are thought to be at higher risk for development of lead-induced seizures.

CLINICAL SIGNS

The primary signs seen with lead intoxication in dogs and cats are related to GI upset. Anorexia, vomiting, diarrhea, weight loss, lethargy, and abdominal discomfort have been reported. In cats the most common signs are lethargy and anorexia. Neurologic signs may also occur but are less common than GI signs. Neurologic effects can include behavior changes, ataxia, tremors, seizures, and agitation. Less commonly other signs such as polyuria, polydipsia, blindness, aggression, dementia, pica, vestibular signs, coma, and megaesophagus (cats) have been reported.

LABORATORY AND RADIOGRAPHIC FINDINGS

In acute lead intoxication very few changes in clinical pathology parameters would be expected. Anemia, basophilic stippling, and elevations in nucleated red blood cells have been reported as indicative of lead toxicosis; but these abnormalities are not consistently found, nor are they pathognomonic for lead toxicosis. Basophilic stippling and nucleated red blood cells (>40 NRBCs per 100 white blood cells) are considered to be more likely to occur in dogs and less likely to occur in cats with lead toxicosis.

Radiography may be helpful in identifying lead opacities within the GI tract. *Lead lines*, linear opacities in the epiphyses of long bones used to aid in diagnosis of lead toxicosis in humans, are not commonly found in domestic animals.

PATHOLOGIC FINDINGS

Few gross lesions have been described in dogs and cats with lead toxicosis. Necropsy may reveal the presence of lead objects especially in the GI tract. Histopathologic findings may include degenerative changes within the white matter of the brain and spongiosis of the cerebrum. In dogs degenerative changes in the kidney and liver may be seen, occasionally associated with intranuclear inclusion bodies.

Diagnosis

The diagnosis of lead toxicosis can be difficult because the signs most commonly associated with this disease (anorexia, lethargy, vomiting) are nonspecific. Blood lead levels can be measured in a timely fashion and, when evaluated in light of compatible clinical signs, can be helpful in making a diagnosis. The widespread distribution

of lead throughout the body can result in fluctuating blood levels, and the level of lead in the blood may not be indicative of the total body burden. Some animals may have fairly high blood lead levels without significant clinical signs, whereas other animals may have significant clinical signs with only moderately elevated blood lead levels. Most animals have a background lead level of 10 to 15 mcg/dl (0.1 to 0.15 ppm); blood lead levels exceeding 30 to 35 mcg/dl (0.3 to 0.35 ppm) along with appropriate clinical signs are suggestive for lead toxicosis. Levels greater than 60 mcg/dl are generally considered diagnostic for lead toxicosis.

TREATMENT

Management of lead toxicosis entails control of immediate clinical signs, removal of the source of lead, chelation therapy, supportive care, and removal of lead from the animal's environment. Seizures should be managed with anticonvulsants such as diazepam or barbiturates (see Chapter 231). Similarly, vomiting and diarrhea should be managed, and any fluid and electrolyte abnormalities should be corrected as needed.

GI decontamination must occur before chelation therapy since most chelators, with the exception of succimer, will actually enhance the absorption of lead from the GI tract. Sulfate-containing cathartics (magnesium sulfate, sodium sulfate) may be administered to aid in emptying the GI tract and to precipitate the lead as lead sulfate, which is poorly absorbed. Large lead-containing objects (e.g., lead sinkers, lead weights) may require removal via endoscopy or gastrotomy/enterotomy if they are too large to pass using bulking cathartics. When cats are suspected of exposure through grooming, thorough bathing should be performed.

Chelation therapy is intended to bind lead into a soluble complex that will be excreted via the urine. Because of the nephrotoxic nature of most chelators, as well as the lead chelate, it is imperative that renal parameters be assessed before and during chelation and that adequate hydration be maintained during chelation. Chelation of asymptomatic animals that have elevated blood lead levels is not recommended because the chelator may increase the blood lead level and precipitate clinical signs. In cases of asymptomatic animals with elevated blood lead levels, decontamination and removal from the source of lead will allow the animal to eliminate the lead at its own pace.

Available chelators include calcium disodium ethylene diamine tetracetate (Ca-EDTA), British anti-Lewisite (BAL), penicillamine, and succimer (meso-2,3-dimercaptosuccinic acid). Ca-EDTA was the first chelator agent used for lead toxicosis, and it has an established track record in veterinary and human medicine. Sodium EDTA should not be used for chelation because it will bind serum calcium and cause hypocalcemia. Ca-EDTA is administered parenterally and may cause pain at the injection site. The dosage for dogs is 100 mg/kg/day for 2 to 5 days (not to exceed 2 g per dog per day), with each dose divided every 8 hours, diluted to a final concentration of 10 mg of Ca-EDTA per milliliter of 5% dextrose and administered subcutaneously at different sites. Expect clinical improvement within 24 to 48 hours. If further treatment

is required after the first 5 days of therapy, a 5-day hiatus is recommended between treatments. Oral zinc supplementation may minimize the GI side effects of Ca-EDTA. The dose of calcium EDTA for cats is 27.5 mg/kg in 15 ml of 5% dextrose subcutaneously every 8 hours for 5 days.

BAL is occasionally used in combination with Ca-EDTA, especially when significant CNS signs are present. BAL increases both urinary and biliary excretion of lead. BAL is contraindicated in animals with hepatic dysfunction, is nephrotoxic, and causes pain on injection. Other potential side effects of BAL include vomiting, hypertension, sulfur odor of breath, and seizures. The dosage of BAL is 2 to 5 mg/kg intramuscularly every 4 hours for 2 days, then every 8 hours for 1 day, and then every 12 hours until recovery.

Penicillamine is an oral medication that eliminates the need for painful injections of BAL and Ca-EDTA. Penicillamine will bind essential nutrients such as zinc, iron, and copper; and its chelates may be nephrotoxic. Side effects reported with penicillamine include vomiting, fever, lymphadenopathy, and blood dyscrasias. Reported dosages for dogs are 30 to 110 mg/kg/day orally, divided every 8 hours for 7 days, and followed by a 7-day hiatus before reinstitution. Feline dosage is 125 mg per cat orally every 12 hours for 5 days.

Succimer is an analog to BAL, and it has several advantages over BAL, Ca-EDTA, and penicillamine. Succimer can be administered orally or in vomiting animals rectally. Succimer is much less likely to cause nephrotoxicosis than the other three chelators; and it does not bind essential minerals such as copper, zinc, calcium, and iron. Succimer does not enhance absorption of lead from the GI tract as do the other chelators, and it has been shown to decrease lead absorption in studies with rats. Succimer also has a lower incidence of GI side effects. It does impart a mercaptan odor to the breath, similar to BAL. The dose is 10 mg/kg orally or rectally every 8 hours for 10 days.

Following chelation therapy, blood lead levels may show a rebound within 2 to 3 weeks as a result of redistribution of lead from bone and tissue stores. Provided that this rebound is not associated with significant clinical signs, further chelation is not indicated. However, it is prudent to have the animal's environment evaluated to be sure the rebound is not caused by re-exposure to lead.

Supportive care involves providing adequate nutritional support since many animals with chronic lead toxicosis may be in a negative nutritional state because of chronic anorexia and vomiting. Hydration should be maintained, and force- or hand-feeding provided as needed.

Examination of the animal's environment is important to identify and remove any additional sources of lead so the animal does not become reexposed when reintroduced to its environment.

PROGNOSIS

Provided that prompt and appropriate care is pursued, including removing the source of lead from the animal's environment, the prognosis for animals showing mild-to-moderate signs is favorable. Animals showing severe CNS signs or with repeated exposure to lead may merit a more guarded prognosis.

PUBLIC HEALTH

The relative susceptibility of household pets makes them good sentinel animals for the potential for human exposure to lead. Veterinarians treating lead-intoxicated pets should ensure that pet owners are aware of the potential risk to family members, especially young children, from lead in the environment. Pet owners should be directed to their own health care professionals or public health officials for more information. Information on the risks of lead to human health can be found on the website of the Environmental Protection Agency (www.epa.gov).

CHAPTER 29

Automotive Toxins

KARYN BISCHOFF, *Ithaca, New York*

Various compounds for use in vehicle maintenance that are stored around the home have known toxic properties. An incomplete list of such chemicals includes ethylene glycol (EG), propylene glycol (PG), diethylene glycol (DEG), petroleum products, and methanol. EG is the most common component of antifreeze and unfortunately is the most common automotive product associated with poisoning in small animals. PG has been substituted for EG in antifreeze brands that are advertised as “safe” or “nontoxic.” In fact, PG is much less toxic to companion animals than EG but is not without adverse effects.

ETHYLENE GLYCOL

EG is the most common cause of fatal poisoning in small animals (Thrall et al., 2006). EG is readily available in most households, is toxic in low doses, and is palatable. Toxicosis is most common in the late autumn or early spring, when radiators have been drained or open containers may be available to pets. Dogs occasionally chew through closed containers. Denatonium benzoate has been added to antifreeze to make it less palatable. California, New Mexico, and Oregon require addition of bittering agents to commercial antifreeze at the time of this writing.

EG, or 1,2-dihydroxyethane, is a colorless, sweet-tasting liquid with a density of 1.113, a high boiling point (197.2°C), a low freezing point (−12.3°C) and

miscibility with water and alcohol. Other sources of EG include deicer, hydraulic brake and transmission fluids, additives in motor oils, paints, inks, wood stains and polishes, photographic solutions, and solvents used in the plastic industry.

Toxicity and Toxicokinetics

The minimum lethal dose for EG in dogs is about 4.4 ml/kg. Cats are more sensitive, with a minimum lethal dose around 1.4 ml/kg. Dogs are more frequently affected than cats, although cats may be more likely to become intoxicated through grooming activity after dermal contamination. Intact animals are more frequently affected.

EG is absorbed rapidly from the gastrointestinal tract, particularly on an empty stomach. Absorption of injected or inhaled EG is also rapid. Peak plasma concentrations occur within 3 hours of ingestion. Metabolism of EG begins within hours of ingestion and occurs predominantly in the liver, with minor renal and gastric metabolism. The metabolic pathway of EG is illustrated in Fig. 29-1. The metabolism of EG to glycoaldehyde and then glycolic acid to glyoxylic acid are both rate-limiting steps. Oxalic acid is the most important final metabolite of EG. The plasma half-life of EG is approximately 3 hours, and elimination is almost complete within 24 hours. The parent compound—EG—and its metabolites, including glycolic acid and oxalic acid, are eliminated in the urine.

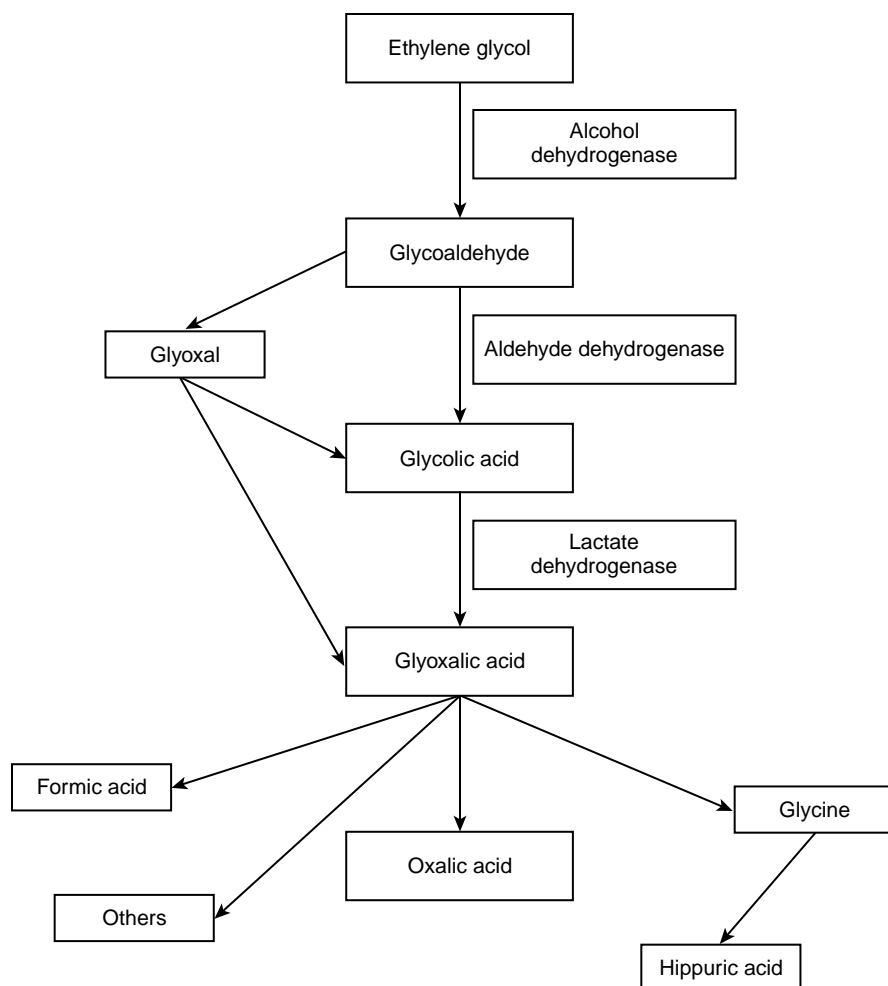

Fig. 29-1 Hepatic metabolism of ethylene glycol.

Mechanism of Action

In itself EG acts as a direct gastric irritant, causes central nervous system (CNS) depression, and may depress respiration. EG may increase serum osmolality, which may contribute to osmotic diuresis. The more severe effects associated with EG ingestion are caused by production of toxic metabolites. Acidosis is produced by such metabolic products of EG as glycolic acid and increased lactic acid production caused by nicotinamide adenine dinucleotide depletion during EG metabolism. Renal tubular damage is the most common cause of death in small animals poisoned with EG. Metabolites of EG are directly cytotoxic to renal tubular epithelium. Oxalic acid binds to calcium ions (Ca^{++}) in the renal tubules (and other tissues) to form calcium oxalate crystals, leading to obstruction of tubules, epithelial damage, and hypocalcemia. Renal blood flow may be compromised in acidosis.

Clinical Signs

EG toxicosis is described as having three stages, although early stages may be missed and stages may overlap. The first stage usually occurs within 30 minutes of exposure and usually lasts for 2 to 12 hours. Animals may vomit early. Polyuria and polydipsia are described in dogs, and cats are frequently polyuric. Ataxia and hyporeflexia may

be apparent, and animals are sometimes described as “inebriated” at this stage. Dogs may show apparent recovery from CNS depressive effects, but cats typically do not.

The second stage usually occurs 8 to 24 hours after exposure and is related to acidosis. Clinical signs at this stage include CNS depression, changes in heart rate, hypothermia, muscle fasciculations, and sometimes coma. Cats may lose coordination in the pelvic limbs.

Small animals that survive the first two stages enter the third stage, acute renal failure. This stage begins within 1 to 3 days of EG ingestion. Animals progress through oliguria to anuria. Signs of uremia may include oral ulcerations, salivation, vomiting, anorexia, and seizures. Palpation of cats often reveals large, painful kidneys.

Serum chemistries often reveal an increased osmolal gap about an hour after EG ingestion, which may decline by 18 hours after exposure. The anion gap increases a few hours after exposure and can remain elevated for 48 hours in animals with acidosis. Phosphorus may be elevated early as a result of the phosphate additives in anti-freeze and during renal failure. Hypocalcemia is reported in some patients. Serum urea nitrogen and creatinine are elevated 1 to 2 days after exposure in dogs and often within 12 hours in cats. Hyperkalemia occurs with the onset of renal failure. Urinalysis reveals isosthenuria as early as 3 hours after exposure as a result of osmotic

diuresis and low urine pH. Calcium oxalate crystals are evident within the first 8 hours, although crystalluria may be evident in healthy animals. Other findings may include hematuria, proteinuria, glycosuria, and granular and cellular casts.

Diagnosis

Speed is of the essence in the diagnosis of EG toxicosis. The prognosis decreases precipitously with time if treatment is not instigated. EG concentrations begin to decline within 6 hours of exposure and may no longer be detectable in blood or urine by the time the animal presents to the veterinarian, which complicates the diagnosis.

Various analytic tests have been used to confirm exposure to EG. Commercial test kits are available, but these may cross-react with certain compounds, including PG and glycerol from pet foods and pharmaceuticals. It is best to collect samples for testing before treatment begins. Test kits are unable to detect EG at concentrations below 50mg/dl and thus may not be sensitive enough to use on cats or on dogs exposed more than 12 hours previously. Gas chromatography (GC) is frequently used to assay blood, urine, or kidney tissue for EG at diagnostic laboratories; but results are delayed by sample shipping and processing.

Concurrent increase in the anionic and osmolal gap with the appropriate history and clinical signs is highly suggestive of EG toxicosis but does not always occur. Calcium oxalate monohydrate crystals are commonly found in the urine. Fluorescent dye is *sometimes* added to commercial antifreeze and may be seen with a Wood's lamp in the urine or around the oral cavity or vomitus of exposed animals. However, other components of urine and some plastic containers may fluoresce.

Finding the "halo effect" on renal ultrasound has been used to support an EG diagnosis. This is described as increased echogenicity in the cortex and medulla with decreased echogenicity at the corticomedullary junction and central medulla and occurs near the onset of anuria.

Postmortem findings typical of EG exposure may include gastric hemorrhage; pulmonary edema; and pale, firm kidneys. Histologic changes include degeneration and necrosis of the epithelium of proximal convoluted tubules with intraluminal birefringent crystals. Chronicity is indicated by evidence of tubular regeneration, interstitial fibrosis, and glomerular atrophy and synechia. Oxalate crystals may be found in other tissues, including the liver and CNS.

Management

The prognosis for EG toxicosis depends on the time of presentation. Animals treated early (stage 1) have an excellent prognosis, but the prognosis is poor for animals that present in renal failure (stage 3).

Gastrointestinal decontamination, including emetics or gastric lavage and activated charcoal orally, has been recommended for animals within a few hours of EG ingestion. The benefit of such treatment is questionable because of the rapid absorption of EG.

Antidotes are available for EG. They act by inhibiting metabolism of EG by alcohol dehydrogenase (Bonagura, 2000). Antidotal treatment is most effective when started early but recommended if exposure has occurred within the past 32 hours. Fomepizole, or 4-methyl pyrazole, is preferred. This product is used in dogs at an initial dose of 20 mg/kg intravenously (IV); then 15 mg/kg IV is given at 12 and 24 hours, and 5 mg/kg is given IV at 36 hours. Cats require much higher doses of fomepizole than dogs. The recommended dose for cats is 125 mg/kg IV initially and then 31.25 mg/kg every 12 hours for three more doses. Benefits of fomepizole include its lack of CNS depressant effects and the rarity of adverse effects. Fomepizole should never be used concurrently with ethanol therapy. Doing so will exacerbate clinical signs of ethanol toxicosis. Hemodialysis removes fomepizole from circulation. The prognosis is good if fomepizole therapy is started within 8 to 12 hours of EG ingestion for dogs or within 3 hours for cats. Fomepizole may not be immediately available; thus ethanol is still used therapeutically.

Ethanol competitively inhibits metabolism of EG because of its affinity for alcohol dehydrogenase. It has been used for many years to treat EG toxicosis. Ethanol enhances CNS depression, and bolus dosing may cause respiratory suppression. Animals remain stuporous during treatment, requiring close monitoring and supportive care. Ethanol is usually given IV to maintain blood concentrations of 50 to 100mg/dl. A 5.5-ml/kg dose of 20% ethanol is given every 4 hours for the first five treatments and then every 6 hours for the next four treatments in dogs, or dogs may be given a bolus dose of 1.3 ml of 30% ethanol followed by a constant infusion rate of 0.42 ml/kg/hour for 48 hours. Cats are given 5 ml/kg of 20% ethanol IV every 6 hours for five treatments and then every 8 hours for four treatments.

Patients should be monitored for hydration, urine production, acid-base status, serum urea nitrogen, creatinine, electrolytes, and body temperature at least daily. Bladder catheterization may be needed to monitor urine production. Fluid therapy is used to correct dehydration and electrolyte imbalances and promote diuresis. Saline is used to establish urine flow in anuric patients before potassium is added. Slow infusion of bicarbonate solution is required to correct acidosis. B vitamins (pyridoxine and thiamine) are routinely added to fluid therapy regimens in humans to promote glyoxylic acid metabolism.

Peritoneal dialysis and hemodialysis have been used in veterinary and human medicine to treat renal failure, although fomepizole therapy must be adjusted. Tubular regeneration requires weeks or months, and the animal's urine concentrating ability may be lost for more than a year.

PROPYLENE GLYCOL

PG, or 1,2 propandiol, is used in commercial antifreeze as an alternative to the more toxic EG. PG is also used as a deicer, hydraulic fluid, industrial solvent, humectant, and plasticizer, as well as in pharmaceuticals, cosmetics, and foods. It is commonly used as antifreeze in recreational vehicles. PG may be kept in large barrels in veterinary

clinics as a treatment for ketosis in ruminants. PG is classified as “Generally Recognized As Safe (GRAS)” by the U. S. Food and Drug Administration but is no longer used in cat food.

PG has a density of 1.036 and is colorless, odorless, and almost flavorless. Like other antifreeze compounds, it has a high boiling point (189°C) and a low freezing point (−60°C) and is freely miscible with water and alcohol.

Toxicity, Toxicokinetics, and Mechanism of Action

PG is less toxic than other glycols. Laboratory animal LD₅₀s tend to fall near 20 ml/kg. The median lethal dose in experimental dogs is 9 ml/kg. Dogs tolerate a diet containing up to 20% PG with minimal clinical effects; however, 5% to 6% PG in the diet causes increased Heinz body formation in kittens and cats. High doses (approximately 40% of the diet) have been associated with mild neurologic signs, including ataxia and depression in cats. Toxicosis has been reported in humans, horses, and cattle and experimentally produced in cats, dogs, laboratory animals, goats, and chickens. I have seen apparently malicious poisoning in dogs using PG.

PG is absorbed rapidly from the gastrointestinal tract and lungs, after injection, and through damaged skin. The volume of distribution is 0.5L/kg in humans. About one third of PG is excreted unchanged in the urine; the rest is metabolized mostly in the liver and kidneys. Lactic acid is one major metabolite. PG may be conjugated to glucuronide in some species, but this metabolic pathway is inadequate in cats. Metabolites usually appear in the blood within 4 hours of exposure. PG may be excreted completely within a day in dogs.

PG causes osmotic diuresis and a direct narcotic effect similar to ethanol but at about one third the potency. Lactic acid, the metabolic product, is formed in 2 isomers. The L- isomer enters the citric acid cycle and is metabolized. D-lactic acid is not readily metabolized and contributes to lactic acidosis. The mechanism of PG-mediated Heinz body formation and the dose-dependent decrease in survival time for feline erythrocytes are not completely understood.

Clinical Signs and Diagnosis

Clinical signs in cats given high doses of PG include polyuria, polydipsia, and mild-to-moderate ataxia. Cats exposed to low dietary concentrations of PG may be asymptomatic but frequently have increased numbers of Heinz bodies, reticulocytes, and low red blood cell counts. Increased blood concentrations of D-lactic acid occur at higher dietary levels of PG.

Clinical signs of acute PG toxicosis are referable to acidosis. Osmotic diuresis is present in animals after oral or parenteral administration of PG. Hypotension and circulatory collapse have been reported in cats and other species after parenteral overdosing. Pure PG is hyperosmolar and is likely to cause hemolysis if given undiluted IV. Postmortem lesions are nonspecific but may include a foul, garliclike odor to gastrointestinal contents after PG ingestion.

Diagnosis is based on history and clinical signs. Serum, urine, tissues, or the suspected source of PG may be analyzed using GC.

Management

The prognosis for cats with chronic dietary exposure to PG is excellent. The number of Heinz bodies decreases once the source of PG is removed. The prognosis for acute toxicosis is fair to guarded, depending on the status of the animal. Decontamination using gastric lavage and activated charcoal may be effective if implemented very early, but gastrointestinal absorption is quite rapid. Dehydration, acidosis, and hypoglycemia are treated routinely as needed. Antioxidants such as vitamin E and vitamin C have been given to prevent erythrocyte damage without satisfactory results. N-acetylcysteine therapy has shown minimal benefit.

DIETHYLENE GLYCOL

DEG is an industrial solvent that may be present in brake fluid, hydraulic fluid, lubricants, and canned cooking fuels. High mortality is reported in epidemic human poisonings. DEG has a specific gravity of 1.118 and is a colorless, nearly odorless, palatable liquid.

Toxicity, Toxicokinetics, and Mechanism of Action

The median lethal dose of DEG in laboratory animals ranges from 3.6 to 11.6 ml/kg; thus it is more toxic than PG but less so than EG. DEG is rapidly absorbed through the gastrointestinal tract or damaged skin. Peak plasma levels occur within an hour or two. DEG is metabolized primarily in the liver by alcohol dehydrogenase and aldehyde dehydrogenase. DEG and metabolites are excreted in the urine, and excretion is almost complete within 36 hours. The mechanism of action of DEG is not understood. There is a direct narcotic effect and renal damage, but oxalate crystals are not produced.

Clinical Signs and Diagnosis

Clinical signs of DEG toxicosis are similar in most species. CNS depression and vomiting are reported early. These clinical signs appear to resolve but are followed by renal failure after 1 or more days. Cardiac abnormalities have been reported in some species. Serum chemistry findings include elevated urea nitrogen, creatinine, potassium, and evidence of lactic acidosis.

Findings at necropsy usually include pale, swollen, mottled kidneys that bulge on cut surface. There is necrosis and degeneration of proximal convoluted tubular epithelium and tubular ectasia. Hepatic lipidosis and centrilobular necrosis have been reported in some species. Hemorrhage involving the pericardium, adrenal medulla, lungs, and pleura has been reported in humans, and I have seen similar lesions in one dog.

Diagnosis is based on a history of exposure, clinical signs, and lesions. Tissues or suspected sources of DEG can be tested using GC, keeping in mind that elimination of DEG from the body is very rapid.

Management

Animals presenting soon after exposure to DEG have a fair- to-guarded prognosis; but, once animals have evidence of renal failure, the prognosis is poor. Therapy includes symptomatic and antidotal treatments similar to those described for EG toxicosis.

PETROLEUM COMPOUNDS

Petroleum compounds include a wide variety of products with variable physical and chemical characteristics. Such compounds include fuels such as propane, gasoline, kerosene, and diesel; solvents such as paint thinner and degreasers; lubricants such as motor oil; and carriers for pesticides, paints, and drugs. Animals may ingest spilled hydrocarbons or drink from open containers. Material spilled on the skin may be absorbed. Animals are occasionally given petroleum products intentionally.

Toxicity, Toxicokinetics, and Mechanism of Action

Toxicity for petroleum products is highly variable and dependent on such factors as volatility, viscosity, and surface tension. Highly volatile compounds are associated with more morbidity and mortality because they are more readily aspirated into the lungs or absorbed into systemic circulation. Aspirated products having low viscosity penetrate deeper airways, and low surface tension further enhances spread within the pulmonary parenchyma.

Absorption occurs through the gastrointestinal tract, skin, and lungs. Low-molecular weight compounds such as gasoline are better absorbed; whereas high-molecular weight compounds such as greases, mineral oils, and waxes are not well absorbed. Hydrocarbons are distributed to all major organs. Aliphatic hydrocarbons are oxidized in the liver to polar compounds that are more readily excreted. Respiratory excretion is important for volatile compounds, and highly volatile hydrocarbons may be excreted completely within 24 hours.

Aspirated hydrocarbons dissolve lipids in cell membranes and cause degeneration and necrosis of the respiratory epithelium. Bacterial pneumonia may occur secondarily. Direct irritation of the skin and eyes is caused by the solvent effects of volatile hydrocarbons on cell membranes. Absorbed compound may interact with neuronal cell membranes to cause CNS depression.

Clinical Signs and Diagnosis

Early clinical signs of ingestion include increased salivation, head shaking, and pawing at the muzzle. Vomiting and colic are typically seen with more volatile compounds, and diarrhea with heavier compounds such as mineral oil. Absence of emesis does not ensure that aspiration has not occurred. Signs of aspiration pneumonia may include choking, coughing, gagging, dyspnea, or cyanosis. Signs of CNS involvement include ataxia, confusion, depression, narcosis, and coma. Tremors and convulsions have been reported in a few cases. Cardiac arrhythmia and cardiovascular collapse have also been reported.

Animals that die after hydrocarbon ingestion frequently have gross lesions typical of aspiration pneumonia. Oily material may be visible in small airways. Secondary bacterial infection may be evident in animals that die late in the course of the disease. Centrilobular hepatic necrosis, myocardial necrosis, and renal tubular necrosis have been reported in animals surviving more than 24 hours according to Raisebeck and Daily (2006).

If vomitus or stomach contents from an animal that has ingested hydrocarbons are mixed with warm water, the petroleum compounds float to the top. If skimmed with a paper towel, these compounds evaporate quickly and have a characteristic odor. This odor may be detectable on the breath or skin of the affected animal. Confirmation of exposure involves analysis of the gastrointestinal content or material on the skin and suspected source material via GC. Samples should be collected quickly and placed in glass containers or wrapped in foil to avoid contact with plastic and frozen until analysis can be performed.

Management

The prognosis for animals that have ingested low-volatility compounds such as mineral oil or motor oil is good, assuming these products were not contaminated with other toxins such as pesticides or heavy metals. Management involves cage rest and observation. Animals that have no evidence of aspiration pneumonia 12 to 24 hours after ingestion have a good prognosis. Uncomplicated aspiration pneumonia is usually resolved after 2 weeks. However, the prognosis is poor if animals have extensive pulmonary lesions or present in a comatose state.

Early management involves identification of the compound involved. The owner should bring the container or label of the suspected source of exposure. If contamination is dermal, a mild detergent bath and clipping of long or matted hair are useful. Animals should be kept warm during this process. Use of mechanic's hand cleaner, lard, or similar substances may be required for removal of very viscous products such as tar. If the animal has ingested the material, gastrointestinal detoxification must be pursued with care. Emetics are usually contraindicated because of the risk of aspiration. Gastric lavage in the sedated, intubated animal and dosing with activated charcoal have been recommended. Instillation of mineral oil or vegetable oil to induce catharsis may increase the risk of aspiration pneumonia; thus it should be avoided.

Monitoring of the exposed animal should include auscultation and thoracic radiography to assess pulmonary function. Aspiration pneumonia is treated symptomatically with cage rest, supplemental oxygen, and β_2 -agonists if needed for bronchospasm. Corticosteroids increase the risk of bacterial infection and should not be used. Prophylactic antibiotics should be considered. Cardiac function should be monitored, and arrhythmia treated as needed.

METHANOL

Methanol is used in automotive window washer fluids, gasoline antifreezes, canned cooking fuels, and various solvents. It is highly toxic to humans and other primates,

causing formic acidosis, CNS disturbances, and retinal damage. Methanol is much less toxic to dogs and cats because they have an improved ability to metabolize formic acid using an enzyme system dependent on folate. In fact, it is less toxic in small animals than ethanol. Clinical signs of methanol toxicosis in dogs and cats are similar to those of ethanol inebriation. Treatment is based on monitoring and symptomatic and supportive care. Treatment with ethanol or fomepizole to inhibit alcohol dehydrogenase is discouraged.

CHAPTER 30

Nicotine Toxicosis

WAYNE SPOO, Winston-Salem, North Carolina

Nicotine toxicosis is encountered occasionally in small animals, including dogs and cats. Toxic exposure is likely when a nicotine source is available and ingested in sufficient amounts or when dermal/oral membrane exposure occurs. Nicotine can become available to animals from a variety of sources. This chapter focuses on nicotine toxicosis as it relates to consumption of nicotine replacement products (NRPs) and smoked/unsmoked tobacco products.

SOURCES OF NICOTINE

There are many potential sources of nicotine in nature. Table 30-1 lists possible sources of nicotine in the home. The tobacco plant *Nicotiana* spp. contains significant amounts of nicotine (1% to 6% by dry weight) both during the growing and harvesting cycles and after it has been dried and processed for inclusion in cigarettes, cigars, and other tobacco products. However, dietary plant sources also exist. Davis and colleagues (1991) and Domino, Hornbach, and Demana (1993) found that a number of common food items, principally found in the family Solanaceae (among others), contained varying amounts of nicotine but no cotinine (one metabolite of nicotine).

Others have reported that a number of plants other than tobacco contain nicotine, with estimates reported from 12 families and 24 genera, but at levels substantially lower than those found in tobacco.

Why nicotine is present in plants is not known, but it is speculated to be a natural defense mechanism against bacteria, insects, and some animals. Dietary sources of nicotine are mentioned here as a potential source of exposure from homemade pet foods. Pet foods made with these products may provide an exposure mechanism to nicotine; however, there are no known reports of nicotine toxicosis in animals resulting from such exposures. No reports were identified that specifically linked toxicity related to inhalation of nicotine from cigarette smoke, although literature is available that describes the potential adverse health effects of cigarette smoke in pets.

Nicotine Replacement Products

Food and Drug Administration (FDA)-approved NRPs are used by humans as an aid to quit smoking. The products come in a number of forms and delivery methods, are used to replace nicotine normally inhaled during

Table 30-1

Sources of Nicotine

Source	Form	Specifics
Diet	Homemade pet foods, scraps, garbage	Tomatoes (canned or fresh), green peppers, potatoes, eggplant, cauliflower
Tobacco	Smoke	Environmental tobacco smoke or “second-hand” smoke
Tobacco	Unsmoked tobacco products	Cigars, cigarettes, snuff, chewing tobacco
Cigarette structural materials	Smoked and unsmoked tobacco products	Cigarette butts (i.e., filter, plug wrap, tipping paper from smoked cigarettes)
Smoking cessation products	Transdermal patches, gum, lozenges, etc.	FDA-approved nicotine replacement products (see Table 30-2)

FDA, Food and Drug Administration.

Table 30-2

Typical Nicotine Replacement Products Available in the United States

Product Type	Product Name	Approximate Nicotine Content*	Availability
Patch	Habitrol, Nicoderm, Prostep, store brand or generic	7, 14, and 21 mg delivered dose/24 hr	Over-the-counter
Gum	Nicorette, store brand or generic	2-4 mg/stick	Over-the-counter
Nasal spray	Nicotrol	0.5 mg/spray	Prescription
Inhaler	Nicotrol	4 mg/cartridge	Prescription
Lozenge	Commit, store brand or generic	4 mg/lozenge	Over-the-counter

*Nicotine levels reported here are estimates for comparison only and may vary with brand and delivery method.

smoking, and are intended for short-term use. Table 30-2 is a partial list of some NRPs available in the United States and can be used by clinicians as a guideline to determine potential exposure to nicotine via the devices. A complete list of FDA-approved NRPs can be found at the FDA’s website.

Nicotine dosage can be estimated when the number of gums, lozenges, or sprays/inhaler exposures are known. With respect to NRP patch products, the manufacturer label typically reports the dosage of nicotine delivered transdermally in humans over a 24-hour period. In the case of oral exposure in animals, the total amount of nicotine contained in each patch is of most relevance; however, dosage estimation can be a challenge. This information is not reported on the label and is known to vary between manufacturers. For example, Habitrol (Novartis) delivers 7, 14, and 21 mg of nicotine per 24 hours in humans; however, the patches contain total amounts of 17.5, 35, and 52.5 mg of nicotine, respectively. Nicoderm CQ (Glaxo-Smith-Kline) reports to deliver the same 7, 14, and 21 mg of nicotine per 24 hours in humans as well; however, the patches contain total amounts of 36, 78, and 114 mg of nicotine, respectively. Practitioners should consider calling the manufacturer directly to help determine the approximate ingested dose of nicotine or contact a poison control center to obtain information about total nicotine content of an ingested product.

Tobacco

Whole cigarettes or cigarette butts are available sources of nicotine for pets within the household; tobacco products such as cigars, snuff, plug, and pipe tobacco are also potential sources. Nicotine content in tobaccos varies considerably among the types and brands of tobacco, and the list is too extensive to show here. Table 30-3 lists some general values for each of these types of tobacco and should be used as a guideline only. Other alkaloids in addition to nicotine are also found in tobacco at much lower levels,

Table 30-3

Guideline Values for Nicotine Content by Type of Tobacco

Product Type	Nicotine Content (Dry Weight Value)
Cigarette butt	1.4-1.7 mg
Plug	8 mg/g
Loose-leaf snuff	7-12 mg/g
Cigarettes	10-16 mg/rod*
Moist snuff	3-11 mg/g

*Rod weights vary by brand and style. For comparison purposes, 0.78 g of cut filler tobacco/rod was assumed.

including nornicotine, anabasine, myosmine, nicotyrine, and anatabine, and are not thought to be of toxicologic concern.

NICOTINE TOXICITY

Mechanism of Action, Kinetics, and Clinical Signs

Nicotine is a weak base, which initially inhibits its absorption when ingested. Little absorption occurs in the stomach because of low pH but likely increases as the nicotine enters the less acidic intestines. Despite these considerations, substantial amounts of nicotine are systemically absorbed after ingestion. Relatively better absorption is obtained from dermal and oral mucosa exposure. Nicotine is metabolized in the liver. Nicotine mimics acetylcholine, acting at the parasympathetic and sympathetic ganglia and the neuromuscular junctions. Clinical signs of toxicity at less than lethal doses include hyperactivity, vomiting, and salivation. As the dose increases, tremors, dyspnea, tachycardia, muscle weakness/paralysis, and death from respiratory paralysis ensue.

CLINICAL NICOTINE TOXICITY

Reports of clinical toxicity related to nicotine in animals are few, mainly limited to dogs. Less information is available for cats and birds. The median lethal dose (LD_{50}) in dogs is reported to be 9.2 mg/kg (Franke and Thomas, 1932). Clinical signs of toxicity have been reported to begin in the 1- to 2-mg/kg range (Osweiler, 1990), and a minimum LD in dogs and cats was reported to be 20 to 100 mg. Using these data, a 40-lb dog would need to ingest approximately 11 cigarettes to reach the LD_{50} dose (assuming 100% absorption) or one cigarette to achieve signs of clinical toxicity.

Vig (1990) reported nicotine toxicosis in a 12-week-old toy poodle that ingested approximately 1 tbsp of liquid from a spittoon. The dog presented with constricted pupils, central nervous system dysfunction (incoordination, trembling, opisthotonus), salivation, and increased heart rate. Blood nicotine and cotinine levels were not reported. Nicotine toxicosis was the most likely diagnosis; however, further characterization of the liquid that was ingested for nicotine content or other potentially toxic components was not reported. Treatment was symptomatic with oral activated charcoal, intravenous diazepam, and sodium bicarbonate. Fourteen hours after admission, the dog's clinical appearance was normal.

Matsushima, Prevo, and Gorsline (1995) reported on the adverse effects of nicotine after topical and oral administration of three transdermal nicotine products. Nicotine doses ranged from 1 to 2 mg/kg/day when dosed topically, resulting in plasma nicotine levels as high as 43 ng/ml. Two of 12 dogs exposed via this route exhibited mild clinical signs consisting of excessive salivation and emesis. When the patches were administered orally (2.8 mg/kg for one patch; 13.4 mg/kg for two patches) over 25 to 57 hours, mean plasma nicotine levels peaked within 1 to 2 hours after administration, with plasma nicotine levels roughly similar to that of the dermal route.

Two of the 12 dogs receiving two patches orally vomited. Other physiologic observations (e.g., heart rate, blood pressure) were not reported.

Cardiovascular effects related to nicotine have also been reported. Huckabee and associates (1993) reported increased regional blood flow in anesthetized dogs dosed with 3 to 100 mg/kg of moist snuff placed in the right buccal space. The nicotine content on the moist snuff on a per gram basis was not reported; thus the exact dose was unknown (see Table 30-3 for an estimated value). Moist snuff increased blood in the buccal tissue at the site of application, with a decrease in blood flow in the opposite (undosed) buccal space. In contrast to oral exposure scenarios, increases in aortic blood pressure, central venous pressure, and left ventricular diastolic and systolic pressure tended to increase as the dose of snuff increased. Similar cardiovascular findings in dogs were reported by Herman and colleagues (2001) using various nicotine patches and Skoal Bandits (moist snuff in a small pouch) placed in the buccal cavity. Nicotine has also been reported to alter renal function in dogs (Pawlik, Jacobson, and Banks, 1985) and elevations in serum angiotensin-converting enzyme (Sugiyama, Yotsumoto, and Takaku, 1986).

It is difficult to describe a typical toxicity scenario associated with nicotine-containing products related to household pets because of a lack of specific poisoning cases and dose information. It is reasonable to conclude that clinical signs related to nicotine toxicosis are likely to be less severe when ingesting cigarettes and/or cigarette butt(s) if treated quickly after ingestion. Signs manifested after ingestion of NRPs are likely to be more overt if the products are damaged and more nicotine is available for absorption versus the intact product (see Table 30-2) or if treatment is delayed. Animals that chew on tobacco products and do not swallow or are otherwise exposed via the oral mucosa only (i.e., puncturing a nasal inhaler) may also exhibit more severe clinical signs, which again depends on the product form.

TREATMENT OF NICOTINE TOXICOSIS

There is no specific treatment for nicotine poisoning; thus therapy is symptom specific. Given the basic nature of nicotine, oral absorption for the stomach is expected to be low, increasing as the nicotine reaches the intestinal tract. If ingestion of nicotine-containing products is suspected/known, evacuation of the gastric contents (if not contraindicated) should be instituted as soon after exposure as possible (see Chapter 24). Gastric lavage, activated charcoal therapy, and supportive care (e.g., fluid therapy, respiratory support) should also be considered. Atropine and benzodiazepines can also be used to counter parasympathetic stimulation. In cases of dermal exposure the nicotine source should be removed, the skin thoroughly washed with soap and water, supportive care administered, and the animal observed for signs of nicotine toxicosis.

Overall, consumption of nicotine from tobacco or NRPs is an occasional poisoning scenario in household pets. Clinical signs related to nicotine toxicity are dose, product, and route dependent. A thorough history related to intoxication, including identification of the specific

nicotine form, estimation of nicotine dose, and time since exposure, is useful in determining treatment protocols and prognosis. Clinicians are encouraged to use Table 30-2 as a guide in determining how much nicotine the animal potentially received. Treatment should be implemented as quickly as possible, and supportive therapy instituted as appropriate.

MINOXIDIL

Minoxidil, a hypotensive agent, has been used as a vasodilator and as a topical solution to enhance localized hair growth in humans. Minoxidil alters potassium channels in vascular smooth muscle, resulting in vasodilation and hypotension. The mechanism of enhanced hair growth is not entirely understood, but minoxidil may increase epithelial cell proliferation at the follicular base or vasodilation of scalp vasculature or both.

Oral formulations of minoxidil are well absorbed orally, with peak plasma concentrations within 2 hours in dogs. When applied topically, 0.3% to 4.5% of the dose is absorbed systemically. Kinetic information regarding

ingestion of the topical product is not available. Although the plasma concentration declines rapidly after peak concentrations, the peak hypotensive effect is delayed by several hours and persists for at least 24 hours after exposure. In humans a large percentage of oral minoxidil is metabolized by conjugation with glucuronic acid. Consequently minoxidil elimination may be delayed in cats if cats eliminate minoxidil in the same way.

In experimental studies in dogs, short-term oral administration of minoxidil resulted in a variety of hemorrhagic and necrotic myocardial lesions, but dermal application of the topical product did not cause cardiac lesions or hypotension. To date significant hypotension in clinical canine cases of minoxidil exposure has only occurred

through ingestion of tablets. Oral exposures to topical products have primarily produced vomiting and lethargy in dogs.

Two cats that had minoxidil solution applied topically showed lethargy and dyspnea within 36 hours of exposure, and pulmonary edema and pleural effusion were identified on radiography. Both cats died in spite of aggressive supportive care. Histopathology confirmed acute myocardial ischemia and edema resulting in severe cardiac compromise, pulmonary edema, and pleural effusion. Whether the minoxidil was absorbed dermally or ingested via grooming behavior is not clear. At least two instances of cats developing hypotension (one with pleural effusion) after licking the treated hair of their owners have been reported to the ASPCA Animal Poison Control Center (ASPCA Animal Poison Control Center, unpublished data). One of these cats died, and the other was lost to follow-up.

Because of the potential for serious cardiovascular compromise, exposures to minoxidil should be managed aggressively. Oral exposures to minoxidil should be managed with gastric emptying followed by activated charcoal. Rinsing the oral cavity with water may bring some relief because the topical solution may be irritating to oral mucous membranes.

Dermal exposures should be decontaminated with bathing in a liquid dishwashing detergent. Bathing may be effective as long as 48 hours after topical exposure because of delayed absorption of topical products. Cardiovascular and respiratory systems should be monitored closely for 36 to 48 hours. Pulmonary edema should be managed using furosemide or other standard treatment. Thoracocentesis may be required to remove pleural effusion and improve respiration. Intravenous fluid therapy is indicated if hypotension develops, although care must be used in managing fluid rates in cats with pulmonary edema. Pressor agents may be useful in hypotensive animals that do not respond to fluid administration alone. The use of colloids (Hetastarch, Gensia Sicor Pharm) at a 5-ml/kg bolus along with dopamine, intravenous crystalloids, and thoracocentesis resulted in successful resolution of pleural effusion and hypotension in one severely affected cat (ASPCA Animal Poison Control Center, unpublished data). The prognosis for animals exposed to minoxidil depends on the extent of exposure, severity of clinical signs, and promptness and aggressiveness of treatment. Animals showing significant cardiac or respiratory signs should be considered to have a guarded prognosis.

XYLITOL

Xylitol is a 5-carbon sugar-alcohol sweetener that is increasingly used in sugar-free products such as gums, baked goods, and candies. In humans xylitol does not cause significant increases in blood insulin or glucose levels. However, in dogs oral xylitol can cause a rapid and dose-dependent increase in blood insulin concentrations, with a concurrent drop in blood glucose concentration. Some dogs that have ingested larger amounts of xylitol-containing products have subsequently developed hepatic necrosis. The mechanistic cause of hepatic lesions has not

been established; however, a theory of interference with hepatocellular adenosine triphosphate production has been raised. The toxicity of xylitol to cats is not known.

Chewing gums with xylitol as the primary or sole sweetener contain about 0.3 to 0.4 g of xylitol per piece. Xylitol doses greater than 100 mg/kg (0.1 g/kg) have been associated with hypoglycemia; and doses greater than 1000 mg/kg of body weight have been associated with hepatic necrosis in dogs.

Clinical signs of hypoglycemia in dogs may occur within 30 minutes of ingesting xylitol-containing products. These signs may include vomiting, lethargy, disorientation, ataxia, tremors, collapse, and seizures. Other signs that may occur include weakness, diarrhea, abdominal pain, vocalization, tachypnea and fasciculation.

Clinical pathologic findings reported in dogs ingesting xylitol include hypoglycemia, hypokalemia, and mild hypophosphatemia. Occasionally hypoglycemia may be prolonged beyond 12 hours, especially in cases of xylitol-containing gum ingestion. Evidence of hepatic insufficiency may be seen by 8 to 12 hours after exposure, characterized by elevations in hepatic enzyme levels. Some dogs develop transient elevations of liver enzymes; whereas others progress to acute liver failure, hemorrhage, dissemination, and death. Not all dogs that develop acute hepatic failure after xylitol ingestion show signs of hypoglycemia. Some simply become acutely ill 48 hours after ingestion of xylitol. Serum chemistry reveals extreme elevations in alanine aminotransferase, elevated bilirubin, and prolonged prothrombin times (PTs) and partial thromboplastin times (PTTs). Some cases show initial hypophosphatemia with terminal hyperphosphatemia.

Management of xylitol exposures in dogs includes gastrointestinal (GI) emptying in asymptomatic dogs. The use of activated charcoal is debatable since results of one in vitro study have indicated that adsorption of xylitol by activated charcoal is limited and unreliable. Because of the potential for significant clinical signs to develop within 30 minutes, emesis and activated charcoal administration must be performed with care to avoid the risk of aspiration. Frequent small meals in asymptomatic animals with frequent monitoring of serum glucose levels for at least 6 to 12 hours are important. Administration of 5% dextrose intravenously (IV) may be needed to maintain normal blood glucose concentrations. Potassium supplementation may be required if potassium levels drop below 2.5 mEq/L.

In dogs ingesting potentially hepatotoxic doses of xylitol (>1000 mg/kg), an initial bolus of intravenous dextrose should be considered, followed by continuous-rate infusion of dextrose for 24 hours, with monitoring of liver enzymes and PT/PTT for 48 to 72 hours. The use of hepatoprotectants (e.g., S-adenosylmethionine) should be considered in dogs developing evidence of injury; although evidence of efficacy of these products in preventing liver injury is lacking, their antioxidant effects may help minimize secondary oxidative hepatic injury. Other standard treatments for hepatic injury (e.g., lactulose, antibiotics) may be required to manage liver injury.

The prognosis for xylitol toxicosis depends on the dose ingested, clinical signs, and the response to therapy. Hypoglycemia generally responds well to dextrose

treatment, but prolonged seizure activity may result in hyperthermia and disseminated intravascular coagulopathy. The development of hepatic necrosis and coagulopathy warrants a guarded prognosis; hyperphosphatemia may be associated with poorer prognosis in dogs.

EXPANDABLE POLYURETHANE GLUE TOXICITY

Expandable polyurethane glues are available as industrial-strength wood glues marketed as Gorilla Glue, Elmer's ProBond Polyurethane Glue, or insulating foam sealants. These products contain diphenylmethane diisocyanate or polymethylene polyphenol isocyanate in various concentrations. The terms *isocyanate* and *diisocyanate* are usually listed in the active ingredient section of most expandable polyurethane glues.

Most glue or adhesive exposures in animals are acute and accidental. All animal species are susceptible; however, dogs are more likely to be involved, presumably because of their chewing habits. Dermal exposure in cats can lead to significant oral exposure after grooming.

Ingestion of expandable polyurethane glues (isocyanates) can form an expanding gastric foreign body. This is more likely to occur in dogs that chew the bottle of glue rather than lick or ingest products covered with the glue. An animal that ingests already polymerized and dried glue is not likely to experience foreign body obstruction.

Most clinical signs develop within 12 hours of exposure but may range from 15 minutes to 20 hours. Radiographic evidence of gastric outflow obstruction can be evident within 24 hours of exposure. The most commonly reported clinical signs of expandable polyurethane toxicosis include vomiting, retching, anorexia, lethargy, visible abdominal distention or presence of a large firm mass on palpation, diarrhea, tachypnea, and dehydration. Following ingestion, the glue polymerizes into a large, friable, black-to-dark brown foreign body. The foreign body may resemble kibble filling the entire stomach. Radiographic findings seen 4 to 5 hours after exposure include a large radiopaque, mottled density in the stomach; gastric dilation; or both. It has been suggested that the expandable polyurethane glue is hygroscopic in nature and absorbs water from the stomach. Warm body temperature may also play a role in glue expansion.

Diagnosis is made based on history of exposure, types of clinical signs present, and endoscopic or radiographic evidence of a foreign body. Before instituting any treatment, it is important to confirm that the patient has been exposed to expandable polyurethane glue versus nonexpandable glue. Cyanoacrylates (Superglue, Krazy glue) that contain ethyl-2-cyanoacrylate or poly (methylmethacrylate) and white glues containing polyvinyl acetate in various concentrations are not known to cause foreign body obstruction following ingestion. Reading the label of the product can be extremely helpful in determining the type of the glue involved. Most expandable glues have the word *isocyanate* or *diisocyanate* written in the active ingredient section.

The treatment of expandable polyurethane glue toxicosis involves (1) decontamination with the aim of preventing formation of a foreign body; (2) determination of

the nature and severity of the foreign body; (3) surgical removal of the foreign body if necessary; and (4) supportive care.

With dermal exposure, the area should be washed thoroughly with a mild dishwashing detergent. The hair is clipped, or the glue manually removed using a toenail clipper. Once the glue dries, it is not normally irritating to the skin.

Induction of emesis with hydrogen peroxide or apomorphine in dogs following oral exposure is debatable. The fear is that, if part of the glue is lodged in the esophagus, it could lead to esophageal obstruction. In our opinion emesis could be tried cautiously under veterinary supervision only if exposure has been within 1 hour. The animal should be given a small amount of water or food after vomiting to clear the esophagus. Dilution with milk or activated charcoal is not recommended because it may enhance both the potential of foreign body formation by providing liquid for the adhesive to absorb and the risk of aspiration from vomiting.

It may be necessary to perform a gastrotomy to remove a gastric foreign body. Abdominal radiographs or endoscopic examination of the stomach may help determine the presence of a foreign body and esophageal and gastric mucosal damage (irritation, ulcers, rupture). Excellent results (100% recovery) have been achieved in dogs with appropriate medical and surgical intervention. Systemic toxic effects other than foreign body obstruction have not been described.

Anesthesia for performing gastrotomy can be induced with propofol (4 mg/kg IV) and maintained with isoflurane. Atropine sulfate is used as a preanesthetic agent (0.02 mg/kg IV). After removal of the foreign body, any damage to the stomach mucosa (i.e., presence of adhesions, ulcers, or rupture) is assessed. Sucralfate, an H_2 antagonist such as famotidine or cimetidine, and broad-spectrum antibiotics are administered after gastrotomy for 10 days or longer, as needed. Metoclopramide can be used for controlling vomiting. Food and water intake should be restricted for the first 12 to 24 hours after surgery. Pain should be controlled, and supportive care given, including intravenous fluids as needed. Several days may be needed for complete recovery after the surgery. Stomach rupture, torsion, and peritonitis are some possible complications following surgery.

BRUNFELSIA SPP. TOXICOSIS

The genus *Brunfelsia* belongs to the Solanaceae family. This plant is an erect, compact, evergreen shrub that grows to about 1.5 to 2 feet in height and diameter. *Brunfelsia* is native to South and Central America and the West Indies. The genus has about 40 different species. All species of *Brunfelsia* in the United States are ornamentals; consequently they are found outside in gardens in warmer regions and inside as potted plants in colder states. The showy flowers appear in clusters. The deep purple flowers gradually change to lavender and then to white over a 3-day period. One plant may have all three flower colors (purple, lavender, and white) at the same time. Brown-green berries can be found in summer and autumn. Each seed pod may possess about 20 small hard seeds.

Although only a few *Brunfelsia* species (*B. calycina* var. *floribunda*, commonly known as *yesterday-today-and-tomorrow*; *B. pauciflora*; *B. australis*; *B. bondera*) have been implicated in animal poisoning cases, all species of this genus should be considered toxic to all animals. All parts (flowers, leaves, berries, and seeds) are toxic. Dogs appear to be particularly attracted to the berries.

There are a few case reports of *Brunfelsia* toxicosis reported in cattle, dogs, rats, and mice. Because of the increased popularity and availability of *Brunfelsia* species in the United States, the numbers of poisoning cases from *Brunfelsia* in the dog appear to be increasing. For example, in 2005 alone, nine *Brunfelsia* toxicity cases were reported to the ASPCA Animal Poison Control Center. Seven of these cases were reported from California, one was from Oregon, and one was from Texas. Most commonly reported clinical signs included seizures, hypersalivation, ataxia, tremors, head shaking, diarrhea, and lethargy. Death was reported in one dog.

The onset time of clinical signs in *Brunfelsia* toxicosis in dogs may occur within 15 minutes to several hours after the exposure. Clinical signs may start with agitation, nervousness, or excitement followed by tremors, shaking, muscular rigidity, paddling, and tonic-clonic seizures. The tonic-clonic seizures and other clinical signs such as muscular rigidity or sawhorse stance may resemble those caused by strychnine poisoning. Clinical signs may last from a few hours up to several days. *Brunfelsia* poisoning does not seem to cause any significant hematologic, chemistry, or pathologic changes in animals.

Although several biologically active compounds have been isolated from *Brunfelsia* species, two compounds of interest are hopeanine and brunfelsamidine. Hopeanine causes decreased activity, paralysis, seizures, and hypersensitivity in rodents; brunfelsamidine produces excitement, tonic and clonic seizures, and death. Brunfelsamidine may prove to be the toxin responsible for neurotoxicity in animals. Other unidentified toxins from *B. calycina* var. *floribunda* are water soluble and maintain toxicity for 4 months.

Diagnosis of *Brunfelsia* toxicosis in dogs may be made based on a history or evidence of exposure to the plant (flowers, leaves, berries, or seeds present in the vomitus, or stool) and presence of characteristic central nervous system (CNS) signs (muscular rigidity, paddling, tonic-clonic seizures). Differential diagnosis list should include strychnine, metaldehyde, methylxanthine, organochlorine pesticides, lead, and illicit drug toxicosis.

The objectives of treatment are decontamination, seizure control, and supportive care. If the animal is presented with CNS signs, the first step should be to stabilize it (control seizures as described later in this paragraph) before starting decontamination or supportive care. Emesis can be induced when no clinical signs are present and exposure is known to have been within 2 hours. Emesis can be induced with hydrogen peroxide or apomorphine and should be followed by administration of activated charcoal. Repeated doses of charcoal every 6 to 8 hours can be useful if seeds or fruit have been ingested. Gastric or enterogastric lavage followed by charcoal administration can be considered when large amounts of seeds or berries have been consumed. Seizures can be controlled

with pentobarbital sodium IV; it should be given to effect and repeated as needed or with methocarbamol (100 to 200 mg/kg IV; maximum dosage of 330 mg/kg/day). Propofol (4–6 mg/kg IV) or diazepam (with variable success) may be used at 1 to 2 mg/kg IV. Isoflurane gas anesthesia should be tried if seizures are not controlled with the preceding treatment measures. Severely affected animals should be intubated, and artificial respiration provided; they should be kept in a dark and quiet place. The animal should be monitored for hyperthermia and treated as needed with cooling bath or fans. Intravenous fluid diuresis may be required for 1 to 2 days or longer. Complete recovery may take several days or a week or longer.

PAINTBALL TOXICOSIS

Dogs seem to be attracted to paintballs. They have been known to eat as many as 500 paintballs at one time. Paintballs are available in different colors, and one box may contain more than 1000 paintballs. Active ingredients vary, depending on the manufacturer, but often include polyethylene glycol, glycerol (glycerin), gelatin, sorbitol, dipropylene glycol, water, dye, titanium dioxide (found in most acrylic paints), and food coloring. Some paintballs have polyethylene glycol available as 94% and dipropylene glycol as 64%; however, concentrations of most ingredients are not listed on the label.

The most commonly reported clinical signs associated with paintball ingestion in dogs include vomiting with or without paint, ataxia, diarrhea, and tremors. Other less frequently seen clinical signs may include tachycardia, weakness, hyperactivity, hyperthermia, blindness, and seizures. Most commonly reported electrolyte changes include hypernatremia (22%), occasionally hyperchloremia, and hypokalemia. Clinical signs can develop within 1 hour to several hours after exposure, and ingestion of as little as 15 paintballs has led to development of clinical signs.

The exact mechanism of hypernatremia or other electrolyte changes following paintball ingestion is not known. It has been suggested that the presence of osmotically active agents such as polyethylene glycol, glycerol, and sorbitol in paintballs can cause fluid shifts, moving the water from the body tissues into the bowel lumen. Clinical signs of hypernatremia, including tremors, ataxia, and seizures, usually start when serum sodium concentration exceeds 160 mEq/L. Sometimes rapid change in serum sodium concentration may be more responsible for clinical signs than the absolute change in serum sodium concentration.

A clinical diagnosis may be based on history or evidence of exposure such as presence of paintballs in the vomitus or stool and presence of clinical signs, including vomiting, ataxia, tremors, and serum electrolyte changes (hypernatremia). Other causes of hypernatremia include salt (sodium chloride) toxicosis, excessive water loss caused by nephrogenic diabetes insipidus, inadequate water intake, heat stroke, and acute or chronic renal failure.

Treatment objectives are decontamination, correction of electrolytes, seizure control, and supportive care. The animal should first be stabilized by controlling seizures

before starting decontamination or supportive care if animal is presented with CNS signs. Emesis can be induced with hydrogen peroxide or apomorphine if the exposure is within 2 hours and if no clinical signs are present. *Do not give activated charcoal* as it does not adsorb sorbitol or most glycols very well. Charcoal administration can also lead to development of hypernatremia in some dogs. After emesis a warm-water enema should be administered at 20 ml/kg to help move the paintballs out of the GI tract. Electrolytes are monitored; and hypernatremia is treated with 5% dextrose, 0.45% or 0.9% saline IV, or lactated Ringer's solution with 5% dextrose. Serum sodium concentration must not be decreased faster than 0.5 to 1 mEq/L/hour since a rapid drop in serum sodium concentrations can cause water influx into the brain and cerebral edema. Other electrolytes should be corrected as needed. Seizures should be controlled with diazepam (0.5 to 2 mg/kg IV as needed). Complete recovery may occur in 24 hours or longer.

GRAPE AND RAISIN TOXICOSIS

Etiopathogenesis

The link between grape or raisin ingestion and nephrotoxicosis in dogs is relatively new. A recent report from the ASPCA Animal Poison Control Center has described the development of acute renal failure (ARF) in 43 dogs following ingestion of fresh or desiccated fruits of the *Vitis* spp. Although the exact nephrotoxic principle found in grapes and raisins currently remains unknown, several theories have been proposed, including the possible presence of pesticide residues, heavy metals, or various molds producing mycotoxins.

Toxicity

Not all dogs ingesting grapes or raisins develop renal failure. The lowest documented grape and raisin dose associated with the development of ARF in dogs is 0.7 oz/kg and 0.11 oz/kg, respectively. A 10-kg dog ingesting 7 oz of grapes would have potential for developing ARF. However, one cannot conclude that these are in fact the lowest doses leading to ARF in dogs.

In terms of exposure, one grape is equal to one raisin, although there are more raisins per unit weight. Although grape and raisin toxicosis has been most commonly described in dogs, there are unconfirmed reports of ferrets and cats developing ARF following ingestion of fruits of the *Vitis* spp.

Clinical Features

In dogs clinical signs occur within a few hours of exposure or can be delayed for up to 24 hours. Commonly reported signs include vomiting (100%), lethargy (77%), anorexia (72%), diarrhea (51%), decreased urine output (49%), abdominal pain (28%), ataxia (23%), and weakness (23%). Clinical signs are quickly followed by characteristic changes in serum chemistry profile.

Clinical chemistry changes observed within 24 hours generally include elevations in serum creatinine and

phosphorus and a higher $\text{Ca} \times \text{P}$ product. By 48 hours after exposure, the blood urea nitrogen (BUN) begins to climb; serum calcium elevations are observed approximately 48 to 72 hours later. A urinalysis may reveal presence of isosthenuria, casts, protein, and glucose. Anuria or oliguria are common sequelae in severe cases and, together with the development of neurologic signs such as ataxia and weakness, generally predict a poor prognosis. Hyperkalemia commonly accompanies oliguria and is associated with metabolic acidosis.

Pathologic Findings

Acute tubular necrosis, particularly of proximal tubules, and dystrophic mineralization of soft tissue may be observed histologically.

Differential Diagnoses

The differential diagnosis for raisin toxicosis includes ethylene glycol toxicity, nonsteroidal antiinflammatory drug (NSAID) toxicity, lily toxicity in cats, infectious diseases such as leptospirosis, bacterial pyelonephritis, hypoadrenocorticism (Addison's), vitamin D/analog ingestion, and chronic renal failure.

Treatment

If ingestion is less than 12 hours and the dog is asymptomatic, removal of the agent from the GI tract is the primary goal. Emesis induction followed by one to two doses of activated charcoal is recommended. In addition, if any grapes or raisins are found in the stool, an enema could be performed to further remove the agent from GI tract.

Intravenous crystalloid fluid diuresis at twice the maintenance rate is recommended to prevent or minimize renal tubular damage for 48 hours or longer. Patients with decreased urine production may require the administration of a loop diuretic such as furosemide, central venous pressure and urine output monitoring, and weighing regularly.

Baseline blood work evaluating renal function should be performed and repeated daily for 2 to 3 days or until the resolution of clinical signs. Monitor serum BUN, creatinine, calcium, phosphorus, electrolytes, bicarbonates, total protein, and a complete blood count. A urinalysis may show the presence of isosthenuria, casts, proteinuria, or glucosuria.

Vomiting can be controlled with an antiemetic such as metoclopramide, and GI protectants such as an H_2 -blocker (famotidine) or a proton pump inhibitor (omeprazole) and sucralfate administered. Hyperphosphatemia can be treated with phosphate binders such as aluminum hydroxide at 30 to 90 mg/kg/day. Magnesium-containing phosphate binders are to be avoided since the renal elimination of magnesium may be impaired with decreased renal function. Placing the patient on a low-protein diet may also be beneficial. If diuresis-refractory oliguria or anuria develops, peritoneal dialysis can be performed and may aid in allowing time for the regeneration of renal tubules to occur.

The prognosis depends on various factors such as severity of exposure; individual susceptibility; preexposure renal

function; and, most important, how quickly the condition is recognized and therapy is instituted. Hospitalization and supportive therapy may be required for days to several weeks. Mortality rate can be high; as nearly 50% of the 43 dogs reported in a recent retrospective study died or were euthanized.

LILY TOXICOSIS IN CATS

Etiopathogenesis

Members of the *Lilium* and *Heimerocallis* genera are considered nephrotoxic to cats, leading to ARF. Implicated species include Easter lilies (*Lilium longiflorum*), tiger lilies (*L. tigrinum*), stargazer lilies (*L. auratum*), rubrum lilies (*L. speciosum*), Japanese show lilies (*L. lancifolium*), as well as daylilies (*Heimerocallis* spp.). Exposure to any part of the plant, including pollen, can lead to toxicosis. Consuming less than one leaf can lead to severe toxicosis. Thus far only cats are known to develop renal failure from lilies. Although the exact mechanism of action for lily toxicity remains elusive, studies suggest that the toxin is water soluble and is more concentrated in flowers than in leaves or other parts of the plant.

Not all plants containing the name *lily* are considered true lilies. As such, neither lily-of-the-valley (*Convallaria* spp.) nor the peace lily (*Spathiphyllum* spp.) belongs to the above-mentioned genera, but they can nevertheless be toxic by a different means. Peace lilies and calla lilies (*Zantedeschia* spp.) contain insoluble calcium oxalate crystals, which can lead to oral irritation and swelling.

Clinical Findings

Signs of lily toxicosis usually develop within 12 hours following exposure, although signs may develop within hours or be delayed for up to 5 days after exposure. Commonly reported signs include vomiting, anorexia, and depression, which typically occur in the hours following ingestion. BUN, creatinine, potassium, and phosphorus concentrations begin rising within 24 to 72 hours after exposure. The creatinine concentration is usually disproportionately elevated when compared to the BUN, with values as high as 53 mg/dl. A urinalysis is helpful in determining if renal tubular damage has occurred and typically reveals isosthenuria, presence of casts, protein, and glucose. Epithelial casts may be seen in the urine by 18 hours after exposure.

Differential Diagnoses

The differential diagnosis of lily toxicosis in cats includes ethylene glycol toxicity, NSAID toxicity, infectious diseases such as leptospirosis, bacterial pyelonephritis, lymphosarcoma and chronic renal failure.

Treatment

Renal failure may be permanent if not treated early. The therapeutic goal is to prevent renal tubular damage

and obstruction secondary to necrosis and sloughing of epithelial cells. The most important first step is to remove plant material from the GI tract. If ingestion is less than 2 hours and the animal is asymptomatic, emesis can be induced. Emesis should be followed with one to two doses of activated charcoal (6 to 8 hours apart) with a cathartic for the first dose and without a cathartic for subsequent administrations. Baseline blood work should be obtained, especially serum BUN and creatinine. Obtaining a urine-specific gravity before treatment is also recommended. Renal function should be monitored daily for a minimum of 2 to 3 days or for as long as needed. Diuresis with lactated Ringer's solution should be initiated at twice maintenance rate of ~130 ml/kg/day for a minimum of 48 hours. Intravenous fluid therapy should be continued longer if symptoms persist. Placing the animal on a low-protein diet is also recommended in the presence of ARF.

Prognosis

Delaying treatment by 18 to 24 hours may result in irreversible renal failure leading to death (or euthanasia) within the following few days. However, with prompt and aggressive treatment renal injury may be prevented. The prognosis is poor when anuria or oliguria develops, but renal function may be restored if peritoneal dialysis is performed. Treatment may be needed for days to weeks for complete recovery.

Human Drugs of Abuse

PETRA A. VOLMER, *Urbana, Illinois*

Animal exposures to human “drugs of abuse” occur periodically in veterinary medicine. In many cases the owners are reluctant to admit that the animal was exposed until it is in severe distress. Often illicit drugs are contaminated with other compounds that may possess pharmacologic activity, causing unique combinations of clinical signs. Diagnosis of a toxicosis is often based on characteristic clinical signs and history of exposure. There has been a recent introduction of over-the-counter drug testing kits available at most pharmacies. These kits are designed for rapid determination of drug presence in urine and, although designed for in-home human use, may provide useful diagnostic information in the veterinary clinical setting. Some kits may test for as many as 12 drugs.

AMPHETAMINES

This class of compounds includes a number of prescription and illicit products, all derivatives of the parent compound amphetamine. Most animal exposures are a result of the accidental ingestion of human prescription products used for the treatment of obesity, narcolepsy, and attention-deficit hyperactivity disorder. Exposure to unlawful amphetamine compounds can also occur. Street names for amphetamine can include *speed*, *uppers*, *dex* or *dexies*, and *bennies*. Methamphetamine production is on the rise in clandestine laboratories in many areas of the United States. Street names for methamphetamine can include *ice* and *glass* for the clear, translucent crystals; and *crystal*, *crank*, and *meth* for the white or yellow powder form. Designer amphetamines include 4-methylaminorex (*ice*, *U4EUh*), methcathinone (*cat*), 3,4-methylenedioxymethylamphetamine (MDMA [*ecstasy*, *XTC*, *Adam*, *MDA*]) and 3,4-methylenedioxymethylamphetamine (MDEA [*Eve*]) (Volmer, 2006; Llera and Volmer, 2006).

The amphetamines as a class are well absorbed orally, with peak plasma levels occurring by 1 to 3 hours; thus clinical signs can develop rapidly. Some pharmaceutical products are extended-release preparations, with the result of prolonging absorption and delaying the onset of signs. Amphetamine and its metabolites are excreted in the urine in a pH-dependent manner, with a lower pH-enhancing excretion (Baggot and Davis, 1972). Amphetamines have a stimulant effect on the cerebral cortex through release of catecholamines, acting as a dopamine excitatory receptor agonist and enhancing release of serotonin. Toxic dosages of amphetamine products are low: the oral median lethal dosage for amphetamine sulfate in the dog is 20 to 27 mg/kg; for methamphetamine hydrochloride it is 9 to 11 mg/kg (Zalis et al., 1965). Signs in field cases can be seen at dosages much lower than experimental lethal dosages.

Exposed animals exhibit signs associated with stimulation. Behavioral effects can include initial restlessness, pacing, panting, and an inability to sit still. These signs can progress to pronounced hyperactivity, hypersalivation, vocalization, tachypnea, tachycardia, tremors, hyperthermia, seizures, and potentially death. In some cases animals may exhibit depression, weakness, and bradycardia.

Diagnosis is based on clinical signs and history of exposure. Amphetamines can be detected in urine. Over-the-counter drug testing kits may be of use in diagnosing an exposure in the acute clinical setting.

Animals should be stabilized and then decontaminated. Animals with known ingestions of amphetamine products less than 30 minutes prior can undergo induction of emesis followed by administration of activated charcoal and a cathartic. Animals already exhibiting signs of stimulation such as restlessness or worse should not be induced to vomit because of the risk of aspiration. Similarly, if the product is rapidly absorbed with the possible rapid onset of signs, emesis is not recommended. For those cases gastric lavage followed by the instillation of activated charcoal and a cathartic is a safer approach. Sustained-release medications may require repeated doses of activated charcoal.

Excitability, tremors, seizures, and other stimulant signs associated with amphetamine intoxication can be treated with acepromazine (0.5 to 1 mg/kg slowly intravenously [IV]; allow 15 minutes for onset of action; repeat as needed) or chlorpromazine (10 to 18 mg/kg IV repeated as needed). Phenothiazine tranquilizers have been shown to have a protective effect when used to treat amphetamine toxicoses (Catravas et al., 1977). Diazepam is not recommended because it can exacerbate the stimulatory signs in some animals. Phenobarbital, pentobarbital, and propofol may also be used to effect to prevent severe central nervous system (CNS) signs. In addition, cyproheptadine, a serotonin antagonist, may be useful to reduce the CNS signs. It has been used successfully to dampen the excessive stimulation from overexposure to antidepressant medications designed to increase serotonin in nerve synapses. Cyproheptadine is dosed at 1.1 mg/kg rectally in dogs.

Tachyarrhythmias should be treated with a β -blocker such as propranolol or metoprolol. Hyperthermia should be corrected using a water mist and fans. Animals should be monitored to prevent subsequent hypothermia. The animal should be housed in a dark, quiet environment to avoid external stimulation.

Intravenous fluids act to protect the kidneys and enhance elimination. Tremendous muscle stimulation

can result in rhabdomyolysis and subsequent myoglobinuria, as well as a metabolic acidosis. Urinary acidification can promote elimination of amphetamines but must not be undertaken if the animal has compromised renal function or if acidosis is already present.

COCAINE

There are two main forms of cocaine: the hydrochloride salt and the pure cocaine alkaloid or *freebase*. The hydrochloride salt is the powdered form. It readily dissolves in water and is usually self-administered by humans either intravenously or intranasally. Some street names for cocaine powder include *coke*, *girl*, *gold or star dust*, *snow*, *blow*, *nose candy*, and *white lady*. Free base is the conversion of the hydrochloride form to the pure cocaine alkaloid. The pure alkaloid thus created exists as a flake, crystal, or rock form that vaporizes when heated, making a popping or cracking sound (i.e., *crack*, *rock*, or *flake*). Freebase is usually smoked but is sometimes taken orally (Volmer, 2006).

Cocaine is rapidly and well absorbed from all mucosal surfaces. Inflamed or irritated surfaces may promote absorption. Cocaine is rapidly and extensively metabolized in the liver and excreted in the urine. Cocaine is a strong CNS stimulant. It acts to block the reuptake of serotonin and norepinephrine and has the ability to block cardiac sodium channels (Parker et al., 1999).

The overall effect of cocaine intoxication is one of stimulation. Animals initially become restless and hyperactive. Signs can progress rapidly to tremors, tachycardia, hypotension, prolongation of QRS intervals, tachypnea, and seizures.

Diagnosis is usually based on clinical signs and history of exposure. Over-the counter drug test kits may be helpful in diagnosing a cocaine toxicosis.

Treatment is aimed at stabilizing the patient followed by decontamination. Because clinical signs can develop rapidly, increasing the risk of aspiration, caution should be used if inducing emesis. A safer approach may be to perform gastric lavage with administration of activated charcoal and a cathartic. Tremors and seizures can be controlled with diazepam, chlorpromazine, or a barbiturate. Pretreatment with chlorpromazine effectively antagonized the effects of cocaine in experimentally dosed dogs (Catravas and Waters, 1981). Administration of sodium bicarbonate decreases the likelihood of development of ventricular arrhythmias, shortens the prolonged QRS complex duration, counteracts the reduction in mean arterial blood pressure, and reverses cocaine-induced sodium channel blockade (Llera and Volmer, 2006). Severe tachyarrhythmias can be treated with a β -blocker such as propranolol. Intravenous fluids should be administered to maintain renal blood flow and promote excretion. Acid-base and electrolyte status should be monitored and corrected. Hyperthermia can be severe in cocaine intoxications. Correction of body temperature can be achieved with evaporative cooling measures such as misting the animal with cool water and placing in front of a fan until normal body temperature is reached or by immersing in a tepid water bath while monitoring body temperature.

MARIJUANA

Tetrahydrocannabinol (THC), the major active cannabinoid in marijuana, can be found in all parts of the marijuana plant. Street names include *pot*, *Mary Jane*, *MJ*, *weed*, *grass*, *puff*, and *hemp*. Hashish is the dried resin from flower tops and can contain up to 10% THC. Hashish oil can contain up to 20% THC. Sinsemilla is seedless marijuana (Volmer, 2006).

THC is highly lipophilic, is highly protein bound, has a large volume of distribution, and is enterohepatically recirculated. All of these characteristics result in slow elimination from the body (Otten, 2002). Only 10% to 15% of THC or its metabolites are excreted in the urine, with the remainder through the feces via the bile. Marijuana has a wide margin of safety, with a minimum oral lethal dose in the dog of greater than 3 g/kg. However, clinical signs can occur at 1000 times less than this dose (Thompson et al., 1973).

Onset of clinical signs can occur within 30 to 60 minutes and can include depression, disorientation, lethargy, ataxia, bradycardia, vomiting, tremor, mydriasis, hypothermia, and urine dribbling. Analysis for THC can be performed on stomach contents and urine.

Treatment is primarily symptomatic and supportive. The cannabinoids have a wide margin of safety, and toxicoses are rarely fatal. If the animal is not exhibiting any clinical signs and no other contraindications exist, emesis should be induced following an ingestion. Because enterohepatic recirculation may prolong the residence time of the cannabinoids in the body, repeated doses of activated charcoal are recommended. Body temperature should be monitored for hypothermia and corrected. In most cases recovery should occur within 24 to 72 hours.

OPIOIDS

Opium, the dried milky exudate of the poppy plant, contains 24 alkaloids, including morphine, codeine, and thebaine. The opioids are synthetic compounds that bind to the opioid receptor and are classed as agonists, partial agonists, or antagonists. They differ in their specificity and efficacy at different types of receptors. Four major opioid receptors have been identified, with most of the clinically useful opioids binding to μ (μ) receptors. Naloxone is a pure competitive antagonist with no agonist activity and has a high affinity for the μ (μ) receptor (Volmer, 2006).

Most animal exposures involve ingestion of pharmaceutical preparations. The opioids are well absorbed from the gastrointestinal tract and rapidly metabolized in the liver. Morphine is glucuronidated, and the glucuronide is then excreted by the kidney. Clinical signs can include vomiting, defecation, salivation, lethargy and depression, and ataxia. In severe cases respiratory depression, constipation, hypothermia, coma and seizures, and pulmonary edema are possible.

Emesis is recommended for recent ingestions in animals that are not exhibiting clinical signs. Pylorospasm produced by the opioid may cause much of the drug to remain in the stomach; thus gastric lavage, activated charcoal, and a cathartic may be effective even several hours

after ingestion. Respiratory depression is the most common cause of death with opioid overexposure and should be treated by establishment of a patent airway, assisted ventilation, and oxygen. Naloxone (0.01 to 0.02 mg/kg IV, intramuscularly, or subcutaneously) reverses respiratory depression but does not restore full consciousness. Naloxone may need to be repeated as clinical signs indicate.

BARBITURATES

Members in this class of compounds are all derivatives of barbituric acid. The barbiturates are used therapeutically as sedatives and anticonvulsants. Animal exposures can result from iatrogenic overdose, ingestion of illicit preparations, accidental administration of euthanasia solutions, and ingestion of euthanized carcasses. Illicit products are known as *downers*, *reds*, *Christmas trees*, and *dolls* (Volmer, 2006).

The barbiturates are well absorbed orally or following intramuscular injection. Lipid solubility of the drug determines the distribution of the barbiturate in the body and the duration of effect. The barbiturates are metabolized in the liver by hepatic microsomal enzymes and excreted in the urine. Acutely the barbiturates may interfere with metabolism of other compounds by binding to hepatic P-450 enzymes, preventing them from acting on other compounds. Chronically barbiturates act to increase microsomal enzyme activity (enzyme induction), thus enhancing the biotransformation of both exogenous and some endogenous substances. Approximately 25% of phenobarbital is excreted unchanged in the urine. It can be ion trapped in the urine by urinary alkalinization, increasing excretion fivefold to tenfold (Haddad and Winchester, 1998). The efficacy of ion trapping for other barbiturates is not as distinct.

Barbiturates activate γ -aminobutyric acid- α receptors and inhibit excitatory glutamate receptors. Clinical signs can include depression, ataxia, incoordination, weakness, disorientation, recumbency, coma, hypothermia, tachycardia or bradycardia, and death. Barbiturates can be detected in stomach contents, blood, urine, liver, and feces.

For recent ingestions in animals exhibiting no other clinical signs, emesis followed by repeated dosages of activated charcoal and a cathartic is recommended. Activated

charcoal acts as a "sink," encouraging the drug to diffuse back into the intestine from the circulation, even for compounds administered parenterally (Plumb, 2005). Gastric lavage followed by activated charcoal and a cathartic is a safer alternative for animals exhibiting clinical signs (and risking aspiration from induction of emesis). Death is usually the result of respiratory depression; therefore intubation, administration of oxygen, and assisted ventilation may be required. Body temperature should be monitored and corrected. Ventricular fibrillation and cardiac arrest can result from some barbiturates and be exacerbated by profound hypothermia (Haddad and Winchester, 1998). Supportive care, including intravenous fluids, is recommended. Forced alkaline diuresis may facilitate the excretion of some barbiturates, especially phenobarbital.

Toxicology of Veterinary and Human Estrogen and Progesterone Formulations in Dogs

MARGARET V. ROOT KUSTRITZ, *St. Paul, Minnesota*

Estrogens and progestins are naturally occurring synthetic hormones that are used therapeutically for a variety of problems affecting the reproductive and other body systems. The use of these hormones can be associated with toxicosis.

ESTROGENS

Estrogen formulations are used in small animal veterinary practice for treatment of urethral sphincter mechanism incontinence and pregnancy termination. Other uses of estrogen include estrus induction in bitches and treatment of prostate disease in dogs (although I have achieved only equivocal success with the former and do not recommend the latter).

The most commonly used forms of estrogen in clinical practice are estradiol cypionate (22 to 44 mcg/kg intramuscularly for pregnancy termination) and diethylstilbestrol (DES; 1 to 5 mg once daily orally for 5 days and then every 4 to 7 days as needed for urethral sphincter mechanism incompetence). Estradiol is the most active endogenous estrogen and is typically administered parenterally. It is metabolized by the liver and eliminated mostly in the urine and to a lesser extent in bile. The half-life of injectable estradiol in humans is 4 days. DES is a synthetic nonsteroidal compound with estrogenic activity. It is usually administered orally, metabolized by the liver, and finally eliminated in urine and bile. The half-life of oral DES in humans is 3 to 4 days.

Acute Overdose/Short-Term Effects

There are no reported studies describing acute toxicity of estrogens in dogs. In humans acute overdose is accompanied by nausea and vomiting. In rats toxicity studies demonstrated kidney or liver failure as the cause of death, with premonitory signs of depression, abnormal gait, and convulsions. The most serious short-term effect of estrogen administration in dogs is pancytopenia. This toxic effect of estrogen is reported to occur more commonly in older animals exposed to high doses of estrogen. However, I am unaware of studies quantifying the term *high* or differentiating a single exposure from chronic administration. Dogs are reported to be more sensitive to toxic effects of estrogen than humans or other animal species.

Estrogen may express a toxic effect on bone marrow directly through receptors for estradiol-1- β . The highest expression of receptors to endogenous estrogen in dogs may be present in canine bone marrow. Estrogen also may induce secretion of a myelopoiesis-inhibitory factor that suppresses replication of granulocyte and macrophage progenitor cells in the bone marrow. Clinically myeloid hyperplasia, evidenced by leukocytosis and thrombocytosis, is followed by myeloid hypoplasia, evidenced by leukopenia; thrombocytopenia; and later normocytic, normochromic, nonregenerative anemia.

In a review of 51 cases of pancytopenia in dogs (Weiss, Evanson, and Sykes, 1999), two (3.9%) were caused by estrogen toxicity. Other causes of pancytopenia in that report were exposure to chemotherapeutic drugs (43.1%), parvovirus infection (9.8%), malignant histiocytosis (9.8%), sepsis (5.9%), immune-mediated hemolytic disease (5.9%), lymphoblastic leukemia (3.9%), and ehrlichiosis (3.9%). Bone marrow suppression also has been reported in dogs with estrogen-secreting tumors of the testes.

Clinical signs of pancytopenia may include lethargy, pale mucous membranes, petechial or ecchymotic hemorrhages, hematuria, hemoptysis, melena, recurrent infections, and fever. Clinical signs and changes in the peripheral blood smear may not develop until up to 3 weeks after estrogen exposure. Definitive diagnosis of estrogen toxicity as a cause of pancytopenia requires knowledge of estrogen exposure. Determination of prognosis may require submission of aspirates or core biopsy specimens from the bone marrow.

Long-Term Effects

Chronic administration of estrogen to bitches in diestrus is associated with increased incidence of pyometra. Exposure to estrogen during pregnancy is contraindicated since estrogen is teratogenic and may be embryotoxic. In humans prenatal exposure to DES is associated with increased incidence of vaginal and cervical clear cell adenocarcinomas and possible increased incidence of testicular neoplasia. In one canine study long-term estrogen therapy was associated with development of ovarian papillary carcinomas. Finally, exposure to estrogen causes transformation of cuboidal or columnar epithelium to squamous epithelium in the genitourinary

tract, including the renal cortex, and the thyroid gland. This squamous metaplasia is associated with secretory stasis and predisposition to prostatitis in dogs but has not been associated with changes in renal or thyroid function.

Therapy for Pancytopenia

Treatment for pancytopenia includes supportive therapy with intravenous fluids and antibiotics. Transfusion of whole blood or specific blood products such as platelet-rich plasma may be required, depending on the animal's clinical presentation. Potential sources of infectious disease should be avoided. Glucocorticoids are contraindicated in these immunosuppressed patients. It may be helpful to consult with a hematologist in difficult-to-manage patients. Resolution may occur within 30 to 40 days but may take several months. An undefined percentage of animals will die.

PROGESTINS

Progestins are used most commonly in small animal veterinary practice for estrus suppression. Other reported uses include treatment of false pregnancy in bitches and paraphimosis in neutered male dogs.

Many progestins are available worldwide since elective ovariectomy is not performed in many countries, leaving medical estrus suppression as the standard of care. Compounds most commonly used in the United States are megestrol acetate (Ovaban, Schering) and medroxyprogesterone acetate. Both are synthetic progestins. Only megestrol acetate is approved for use in dogs in the United States. Megestrol acetate is administered orally and is metabolized slowly by the liver, with a half-life of 8 days. For estrus suppression megestrol acetate is administered at a dose of 0.55 mg/kg once daily orally for 32 days in anestrus or at a dose of 2.2 mg/kg once daily orally for 8 days in early proestrus; note that total dosage is the same.

Acute Overdose/Short-Term Effects

There are no reported studies describing acute toxicity of progestins in dogs. Short-term effects are not life threatening and are reversible on withdrawal of the drug. These changes include lethargy, polyphagia and weight gain, and altered personality.

Long-Term Effects

Progestins administered chronically to dogs can induce adrenocortical atrophy and iatrogenic hypoadrenocorticism. Serum cortisol concentrations are reported to return to normal within several weeks of drug withdrawal. Progestins also may induce insulin resistance and diabetes mellitus in dogs, which may or may not reverse on withdrawal of progestin therapy. Progestins are reported to induce cystic endometrial hyperplasia and pyometra in bitches, although the manufacturer of megestrol acetate claims the prevalence of pyometra to be less than 1% when the product is administered as directed. Finally, dogs are unique in the sensitivity of their mammary tissue to neoplastic change after long-term exposure to progesterone. This effect may be

mediated by growth hormone. Experimental attempts to induce mammary neoplasia in dogs with progestin administration required very long-term exposure to high doses of the compounds used.

Management of progestin toxicosis involves withdrawal of the offending hormone and treatment of any related complications (e.g., pyometra, diabetes mellitus) when possible.

HUMAN ESTROGEN AND ESTROGEN/PROGESTIN MEDICATIONS

Dogs may be exposed to human hormone replacement or contraceptive preparations. Most hormone replacement therapies contain estrogen, and most contraceptives contain either progestins alone or a combination of estrogen and progesterone (Table 33-1). The ratio of estrogen to progesterone in human contraceptive preparation is such that dogs ingesting these medications tend to be overexposed to estrogen. Most human contraceptive pills or tablets contain 20 to 50 mcg of estrogen per unit. Dogs may also be exposed by ingestion of vaginal rings; skin patches; and topical creams or gels containing estrogen, progestin,

or a combination of the two. As with any intoxication, information from the owner regarding the product and amount ingested is invaluable for determination of likelihood of adverse effects. An emetic such as apomorphine may be administered if the ingestion has occurred within 30 minutes.

Short- and long-term effects are as expected for the individual hormones described previously. Adverse effects and complications of long-term use of combination estrogen-progesterone therapies in humans include venous thrombosis, ischemic stroke, and heart disease. There are no reported studies evaluating such effects in dogs.

CHAPTER 34

Herbal Hazards

ELIZABETH A. HAUSNER, *Beltsville, Maryland*ROBERT H. POPPENG, *Davis, California*

The increased use of herbal preparations and the potential for intoxication or adverse events following their use obligate the clinician to consider these substances in cases of suspected poisonings. The incidence of animal toxicoses or adverse events following the use of natural remedies has not been specifically determined in veterinary medicine; however, it is not likely to be higher than the incidence of these effects from many conventional pharmaceuticals.

REGULATIONS

In 1994 Congress passed the Dietary Supplement and Health Education Act (DSHEA) creating a new category of substances termed *dietary supplements*. Dietary supplements include minerals, vitamins, amino acids, herbs,

and any product sold as a “dietary supplement” before October 15, 1994. The Food and Drug Administration (FDA) Center for Veterinary Medicine interpreted the DSHEA as not applying to substances used in animals, leaving veterinary herbals and dietary supplements regulated as foods, food additives, or new animal drugs, depending on the ingredients and their intended use. Herbal products can be marketed as dietary supplements for humans without premarket testing for safety or efficacy, and they can be manufactured without regard to quality control. Consequently variation in the concentration of active ingredient and accuracy of the herbal material used are just two of the potential problems with current herbal or natural products. These problems can alter the efficacy of or potential toxicosis from these products. In contrast, proof of safety and efficacy are required

by the FDA before marketing prescription and over-the-counter (OTC) drugs. In addition, their manufacture is regulated to ensure a consistent product. Of course, nothing prevents a product intended for use in or on humans from being used in or on animals.

INTOXICATION SCENARIOS

Unfortunately, there is almost no information regarding the overall incidence of adverse drug reactions (ADRs) to conventional drugs or herbal remedies in veterinary medicine, and it is likely that ADRs are underreported for both. It is worth noting that in several cases the reported incidence of animal intoxication from an herb, herbal preparation, or dietary supplement seems to parallel its popularity (Ooms, Khan, and Means, 2001; Gwaltney-Brant, Albretsen, and Khan, 2000).

There are a number of scenarios in which animals may experience an adverse reaction to or toxicosis from an herbal preparation.

1. A preparation may contain a known toxicant. For example, the dried rootstocks of *Aconitum* spp. contain several constituents that are acutely cardiotoxic (Lin, Chan, and Means, 2005). Pennyroyal oil containing the putative toxin pulegone was responsible for the death of a dog after dermal application to control fleas (Sudekum et al., 1992).
2. A remedy may contain a toxicant that is not acutely toxic but may be toxic when given chronically. Pyrrolizidine alkaloids are found in many plant species and, when ingested over time, cause severe liver disease (Prakash et al., 1999; Stedman, 2002).
3. Errors may be made when preparing a remedy. For example, an anise seed preparation was contaminated with the highly toxic *Conium maculatum* (poison hemlock) seed (deSmet, 1991). An outbreak of renal interstitial fibrosis in women taking Chinese herbs for weight loss was attributed to the use of *Aristolochia fangchi* instead of *Stephania tetrandia* in imported powdered extracts (Vanderweghem, 1998).
4. Herbal preparations can be intentionally adulterated with chemical contaminants. Many Chinese herbal patent medicines contain drugs such as nonsteroidal antiinflammatory drugs (NSAIDs) or sedatives (Ko, 1998). Also, heavy metal and pesticide contamination has been reported (Ernst, 2002b; Saper et al., 2004). Salmonellosis has been reported in humans taking rattlesnake capsules contaminated with *Salmonella Arizona* (Fleischman, Haake, and Lovett, 1989).
5. The active constituents in herbal preparations can interact with other concurrently administered drugs, resulting in adverse interactions. For example, buckthorn bark and berries taken chronically can increase the loss of potassium, thus potentiating the action of cardiac glycosides and antiarrhythmic agents (DerMarderosian, 2001). Potassium loss may be exacerbated by simultaneous use of thiazide diuretics, corticosteroids, and licorice root (DerMarderosian, 2001). In addition, active constituents in herbal preparations can induce liver-metabolizing enzymes, which can alter the metabolism and kinetics of coadministered conventional drugs. For example, eucalyptus oil induces liver enzyme activity (DerMarderosian, 2001). This scenario of adverse pharmacologic interactions may occur when the owner does not inform the veterinarian of the intentional use of herbal preparations.
6. Finally, pets may consume improperly stored remedies, resulting in ingestion of a large quantity of a product. Ultimately of equal or greater concern than intoxication from herbal remedies is the potential delay in seeking treatment for otherwise treatable diseases.

ACTIVE HERBAL CONSTITUENTS

The following broad classes of active chemical constituents occur in plants: volatile oils, resins, alkaloids, polysaccharides, phenols, glycosides, and fixed oils (Hung, Lewin, and Howland, 1998). Volatile oils are odorous plant ingredients (e.g., catnip, garlic, and citrus). Resins are complex chemical mixtures that can be strong gastrointestinal irritants. Alkaloids are a heterogeneous group of alkaline, organic, and nitrogenous compounds. Glycosides are sugar esters containing a sugar (glycol) and a nonsugar (aglycone). In some cases the glycosides are not toxic. However, hydrolysis of the glycosides after ingestion can release toxic aglycones. Fixed oils are esters of long-chain fatty acids and alcohols. Herbs containing fixed oils are often used as emollients, demulcents, and bases for other agents; in general these are the least toxic of the plant constituents.

There is a misperception that preparations from plants are inherently safe and nonchemical in nature. Many plant-derived chemicals are biologically active and therefore potentially toxic. Concentrated extracts of a number of herbs have proven to be toxic even if the entire plant may be used with relative safety. Although green tea is consumed by many people with apparent safety, an extract of green tea marketed in Europe caused a significant number of adverse hepatic events, including fulminant hepatitis. The extract was withdrawn from the market (Gloro et al., 2005).

TOXICITY OF SPECIFIC HERBS OR OTHER NATURAL PRODUCTS

Some of the most commonly encountered herbals are discussed in the following paragraphs; others are listed in Table 34-1.

Blue-Green Algae

Blue-green (BG) algae are single-celled organisms that have been promoted for their nutritional properties. Several BG algal species produce potent toxins. *Microcystis aeruginosa* produces the hepatotoxic microcystins. *Anabaena flos-aquae* produce the neurotoxins anatoxin-a and anatoxin a₃. *Aphanizomenon flos-aquae* produce the neurotoxins saxitoxin and neosaxitoxin. Efforts are underway to better define the risks associated with ingestion of potentially toxigenic BG algae and to establish safe concentrations of

Table 34-1

Additional Herbs of Toxicologic Concern

Scientific Name	Common Names	Active Constituents	Target Organs
<i>Acorus calamus</i>	<i>Acorus</i> , calamus, sweet flag, sweet root, sweet cane, sweet cinnamon	β -Asarone (procarcinogen)	Liver: potent hepatocarcinogen
<i>Aesculus hippocasteranum</i>	Horse chestnut, buckeye	Esculin, nicotine, quercetin, rutin, saponins, shikimic acid	Gastrointestinal, nervous
<i>Arnica montana</i> and <i>A. latifolia</i>	Arnica, wolf's bane, leopard's bane	Sesquiterpene lactones	Skin: dermatitis
<i>Atropa belladonna</i>	Belladonna, deadly nightshade	Atropine	Nervous: anticholinergic syndrome
<i>Conium maculatum</i>	Poison hemlock	Coniine, other similar alkaloids	Nervous: nicotine-like toxicosis
<i>Convallaria majalis</i>	Lily-of-the-valley, mayflower, conval lily	Cardiac glycosides	Cardiovascular
<i>Cytisus scoparius</i>	Scotch broom, broom, broom tops	l-sparteine	Nervous: nicotinic-like toxicosis
<i>Datura stramonium</i>	Jimsonweed, thorn apple	Atropine, scopolamine, hyoscyamine	Nervous: anticholinergic syndrome
<i>Dipteryx odorata</i>	Tonka, tonka bean	Coumarin	Hematologic: anticoagulant
<i>Euonymus europaeus</i> ; <i>E. atropurpureus</i>	European spindle tree; wahoo, eastern burning bush	Cardiac glycosides	Cardiovascular
<i>Eupatorium perfoliatum</i> ; <i>E. purpureum</i>	Boneset, thoroughwort; joe pye weed, gravel root, queen-of-the-meadow	Pyrrolizidine alkaloids	Liver
<i>Heliotropium europaeum</i>	Heliotrope	Pyrrolizidine alkaloids	Liver
<i>Hyoscyamus niger</i>	Henbane, fetid nightshade, poison tobacco, insane root, stinky nightshade	Hyoscyamine, yoscine	Nervous: anticholinergic syndrome
<i>Ipomoea purga</i>	Jalap	Convolvulin	Gastrointestinal
<i>Mandragora officinarum</i>	Mandrake	Scopolamine, hyoscyamine	Nervous: anticholinergic syndrome
<i>Podophyllum peltatum</i>	Mayapple, mandrake	Podophyllin	Gastrointestinal: gastroenteritis
<i>Sanguinaria canadensis</i>	Bloodroot, red puccoon, red root	Berberine	Gastrointestinal
<i>Solanum dulcamara</i> , other <i>Solanum</i> spp.	Woody, bittersweet, or climbing nightshade	Numerous glycoalkaloids including solanine and chaconine	Gastrointestinal, nervous, cardiovascular
<i>Tussilago farfara</i>	Coltsfoot	PA alkaloid, senkirkine	Liver
<i>Vinca major</i> and <i>V. minor</i>	Common periwinkle, periwinkle	Vincamine	Immune system

total microcystins in marketed products. *Spirulina* has also been promoted as a nutritional supplement and is not considered a toxigenic BG algae genus. However, some products have been found to be contaminated with mercury. Microbial contamination could possibly be a concern if harvested algae grow in water contaminated with human or animal wastes.

Ephedra or Ma Huang

The dried young branches of ephedra (*Ephedra* spp.) have been used for their stimulating and vasoactive effects. In addition, ephedra has been used in several products promoted for weight loss. The plant constituents responsible for biologic activity are the sympathomimetic alkaloids ephedrine and pseudoephedrine. A case series involving intoxication of dogs following ingestion of a weight-loss product containing guarana (caffeine) and ma huang (ephedrine) was recently reported (Ooms, Khan, and Means, 2001). Estimated doses of the respective plants associated with adverse effects were 4.4 to 296.2 mg/kg for guarana and 1.3 to 88.9 mg/kg for ma huang. Symptomatology included hyperactivity, tremors, seizures, behavioral changes, emesis, tachycardia, and

hyperthermia. Ingestion was associated with mortality in 17% of the cases. North American species of ephedra (also called Mormon tea) have not been shown to contain the sympathomimetic alkaloids.

Citrus aurantium ("bitter orange" or "Seville orange") has appeared in many products labeled as "ephedrine-free" and is also combined with caffeine and/or guarana. The primary active components of *C. aurantium* are synephrine (structurally similar to epinephrine), octopamine (structurally similar to norepinephrine), and N-methyltyramine. The overall effect is that of stimulation (Fugh-Berman and Myers, 2004). Studies in humans have shown that bitter orange-containing preparations cause tachycardia and increases in systolic and diastolic pressure (Halle, Benowitz, and Jacob, 2005). Signs of intoxication can be expected to be similar to those seen with ephedra.

Guarana

Guarana is the dried paste made from the crushed seeds of *Paullinia cupana* or *P. sorbilis*, a fast-growing shrub native to South America. The primary active component in the plant is caffeine, with concentrations that range from

3% to 5%, which compares to 1% to 2% for coffee beans. Currently the most common forms of guarana include syrups, extracts, and distillates used as flavoring agents and as a source of caffeine for the soft-drink industry. More recently it has been added to weight-loss formulations in combination with ephedra. Oral lethal doses of caffeine in dogs and cats range from 110 to 200 mg/kg of body weight and 80 to 150 mg/kg of body weight, respectively (Carson, 2001). See Ephedra earlier in the chapter for a discussion of a case series involving dogs ingesting a product containing guarana and ephedra (Ooms, Khan, and Means, 2001).

White Willow

The active constituents in willow (*Salix* spp.) include salicylates (primarily in the form of glycosides salicortin and salicin) and tannins. Current indications for plant use include for fever and rheumatism and as an antiinflammatory. Both therapeutic and adverse effects occur through inhibition of prostaglandin synthesis. In addition, salicylates inhibit oxidative phosphorylation and Krebs cycle enzymes. In cats acetylsalicylic (AS) acid is toxic at 80 to 120 mg/kg given orally for 10 to 12 days. In dogs AS at 50 mg/kg given orally twice a day is associated with emesis; higher doses can cause depression, anorexia, diarrhea, bloody stool, melena, and metabolic acidosis. A dose of 100 to 300 mg/kg orally once daily for 1 to 4 weeks is associated with gastric ulceration; more prolonged dosing is potentially fatal (Osweiler, 1996). Cats are particularly vulnerable to overdose because of an inability to rapidly metabolize salicylates. A number of other plants contain salicylates, including *Betula* spp. (birch), *Filipendula ulmaria* (meadowsweet), and *Populus* spp. See Oil of Wintergreen later in the chapter.

ESSENTIAL OILS

Essential oils are the volatile, organic constituents of fragrant plant matter and contribute to plant fragrance and taste. They are extracted from plant material by distillation or cold-pressing. A number of essential oils are not recommended for use (e.g., aromatherapy, dermal or oral use) because of their toxicity or potential for toxicity (Tisserand and Balacs, 1999). They are listed in Table 34-2. These oils have unknown or oral LD₅₀ values in animals of 1 g/kg or less. Most toxicity information has been derived using laboratory rodents or mice. Such data should only be used as a rough guide since they cannot always be extrapolated to other species. *Essential oil safety: a guide for health care professionals* is an excellent reference for in-depth discussions of general and specific essential oil toxicity. The following essential oils are of particular concern.

Camphor

Camphor is an aromatic, volatile, terpene ketone derived from the wood of *Cinnamomum camphora* or synthesized from turpentine. Camphor oil is separated into four distinct fractions: white, brown, yellow, and blue camphor (Tisserand and Balacs, 1999). White camphor is the form used in aromatherapy and in OTC products (brown and yellow fractions contain the carcinogen safrole and are not normally available). OTC products vary in form and camphor content; external products contain 10% to 20% in semisolid forms or 1% to 10% in camphor spirits. It is used as a topical rubefacient and antipruritic agent. Camphor is rapidly absorbed from the skin and gastrointestinal tract, and toxic effects can occur within minutes of exposure. In humans signs of intoxication include emesis, abdominal distress, excitement, tremors, and seizures followed by central nervous system (CNS)

Table 34-2

Most Toxic Essential Oils

Oil	Genus/Species	Oral LD ₅₀ (g/kg)	Toxic Component (%)
Boldo leaf	<i>Peumus boldus</i>	0.13	Ascaridole: 16
Wormseed	<i>Chenopodium ambrosioides</i>	0.25	Ascaridole: 60-80
Mustard	<i>Brassica nigra</i>	0.34	Allyl isothiocyanate: 99
Armoise	<i>Artemisia herba-alba</i>	0.37	Thujone: 35
Pennyroyal (Eur.)	<i>Mentha pulegium</i>	0.40	Pulegone: 55-95
Tansy	<i>Tnacetum vulgare</i>	0.73	Thujone: 66-81
Thuja	<i>Thuja occidentalis</i>	0.83	Thujone: 30-80
Calamus	<i>Acorus calamus var angustatus</i>	0.84	Asarone: 45-80
Wormwood	<i>Artemisia absinthium</i>	0.96	Thujone: 34-71
Bitter Almond	<i>Prunus amygdalus var amara</i>	0.96	Prussic acid: 3
	<i>Artemisia arborescens</i>	?	Iso-thujone: 30-45
Buchu	<i>Barosma betulina; B. crenulata</i>	?	Pulegone: 50
Horseradish	<i>Cochlearia armoracia</i>	?	Allyl isocyanate: 50
Lanyana	<i>Artemisia afra</i>	?	Thujone: 4-66
Pennyroyal (N. Am.)	<i>Hedeoma pulegoides</i>	?	Pulegone: 60-80
Southernwood	<i>Artemisia abrotanum</i>	?	Thujone: ##
Western red cedar	<i>Thuja plicata</i>	?	Thujone: 85

Data from Tisserand R and Balacs T, 1999.

depression characterized by apnea and coma. Fatalities have occurred in humans ingesting 1 to 2 g of camphor-containing products, although the adult human lethal dose has been reported to be 5 to 20 g (Tisserand and Balacs, 1999; Emery and Corban, 1999). A 1-tsp amount of camphorated oil (\approx 1 ml of camphor) was lethal to 16-month-old and 19-month-old children.

Citrus Oil

Citrus oil and citrus oil constituents such as D-limonene and linalool have been shown to have insecticidal activity. Although D-limonene has been used safely as an insecticide on dogs and cats, some citrus oil formulations or use of pure citrus oil may pose a poisoning hazard (Powers et al., 1988). Fatal adverse reactions have been reported in cats following the use of an “organic” citrus oil dip (Hooser, Beasley, and Everitt, 1986). Hypersalivation, muscle tremors, ataxia, lateral recumbency, coma, and death were noted experimentally in three cats following use of the dip according to label directions.

Melaleuca Oil

Melaleuca is derived from the leaves of the Australian tea tree (*Melaleuca alternifolia*); it is often referred to as tea tree oil. The oil contains terpenes, sesquiterpenes, and hydrocarbons. A variety of commercially available products contain the oil; shampoos and the pure oil have been sold for use on dogs, cats, ferrets, and horses. Tea tree oil toxicosis has been reported in dogs and cats (Villar et al., 1994; Bischoff and Guale, 1998). A recent case report describes the illness of three cats exposed dermally to pure *melaleuca* oil for flea control (Bischoff and Guale, 1998). Clinical signs in one or more of the cats included hypothermia, ataxia, dehydration, nervousness, trembling, and coma. There were moderate increases in serum alanine aminotransferase and aspartate aminotransferase concentrations. Two cats recovered within 48 hours following decontamination and supportive care. However, one cat died \approx 3 days after exposure. The primary constituent of the oil, terpinen-4-ol, was detected in the urine of the cats. Another case involved the dermal application of 7 to 8 drops of oil along the backs of two dogs as a flea repellent (Kaluzienski, 2000). Within \approx 12 hours one dog developed partial paralysis of the hind limbs, ataxia, and depression. The other dog only displayed depression. Decontamination (bathing) and symptomatic and supportive care resulted in rapid recovery within 24 hours.

Pennyroyal Oil

This volatile oil is derived from *Mentha pulegium* and *Hedeoma pulegoides*. Pennyroyal oil has a long history of use as a flea repellent. There is one case report of pennyroyal oil toxicosis in the veterinary literature in which a dog was dermally exposed to pennyroyal oil at \approx 2 g/kg (Sudekum et al., 1992). Within 1 hour of application, the dog became listless, and within 2 hours it began vomiting. Thirty hours after exposure the dog exhibited diarrhea, hemoptysis, and epistaxis. Soon thereafter it developed

seizures and died. Histopathologic examination of liver tissue showed massive hepatocellular necrosis.

Oil of Wintergreen

Wintergreen oil is derived from *Gaultheria procumbens*. The oil contains a glycoside that, when hydrolyzed, releases methyl salicylate. The oil is readily absorbed through skin and is used to treat muscle aches and pains. Salicylates are toxic to dogs and cats. Since cats metabolize salicylates much more slowly than other species, they are more likely to be overdosed. Intoxicated cats may present with depression, anorexia, emesis, gastric hemorrhage, toxic hepatitis, anemia, bone marrow hypoplasia, hypernea, and hyperpyrexia (see Willow earlier in the chapter).

PRODUCT ADULTERATION

There is a long history of Chinese patent medicines being adulterated with metals and conventional pharmaceuticals or containing natural toxins (Ko, 1998; Au et al., 2000; Ernst, 2002a; Dolan et al., 2003). Sedatives, stimulants, and NSAIDs are common pharmaceuticals added to patent medicines with no labeling to indicate their presence. Commonly found natural toxins in Chinese patent medicines include borneol (reduced camphor), aconite, toad secretions (*Bufo* spp., Ch'an Su), mylabris, scorpion-derived toxins, borax, *Acorus*, and strychnine (*Strychnos nux-vomica*) (Ko, 1998).

Chinese patent medicines often contain cinnabar (mercuric sulfide), realgar (arsenic sulfide), or litharge (lead oxide) as part of the traditional formula. Recently dietary supplements purchased largely from retail stores were tested for arsenic, cadmium, lead, and mercury (Dolan et al., 2003). Eighty-four of the 95 products tested contained botanicals as a major component of the formulation. Eleven of the 95 products contained lead at concentrations that would have caused lead intake to exceed recommended maximum levels in children and pregnant women had the products been used according to label directions.

Serious adverse health effects have been documented in humans using adulterated Chinese herbal medicines (Ernst, 2002a). There are no published cases in the veterinary literature, although we are aware of one case in which a small dog ingested a number of herbal tea “balls” that were prescribed to its owner for arthritis. The dog presented to a veterinary clinic in acute renal failure several days after the ingestion. Analysis of the formulation revealed low-level heavy metal contamination (mercury and lead) and large concentrations of caffeine and the NSAID indomethacin. The acute renal failure was most likely to the result of NSAID-induced renal damage.

DRUG-HERB INTERACTIONS

Drug-herb interactions refer to the possibility that an herbal constituent may alter the pharmacologic effects of a conventional drug given concurrently or vice versa. The result may be either enhanced or diminished drug or herb effects or the appearance of a new effect that is not anticipated from the use of the drug or herb alone.

Possible interactions include those that alter the absorption, metabolism, distribution, and/or elimination of a drug or herbal constituent and result in an increase or decrease in the concentration of active agent at the site of action.

For example, herbs that contain dietary fiber, mucilage, or tannins might alter the absorption of another drug or herbal constituent. Herbs containing constituents that induce liver enzymes might be expected to affect drug metabolism and/or elimination (Blumenthal, 2000). Induction of live metabolizing enzymes can increase the toxicity of drugs and other chemicals via increased production of reactive metabolites. The production of more toxic reactive metabolites is termed *bioactivation* (Zhou et al., 2004). Alternatively enhanced detoxification of drugs and other chemicals can decrease their toxicity or their therapeutic efficacy. Long-term use of herbs and other dietary supplements can induce enzymes associated with procarcinogen activation, thus increasing the risk of some cancers (Ryu and Chung, 2003; Zhou et al., 2004). The displacement of one drug from protein-binding sites by another agent increases the concentration of unbound drug available to target tissues. Pharmacodynamic interactions or interactions at receptor sites can be agonistic or antagonistic.

DIAGNOSIS OF HERBAL INTOXICATION

Because of the nonspecific signs associated with most intoxications, the diagnosis of a causative agent is extremely difficult without a history of exposure or administration. Such information may not be forthcoming from clients since they may not equate use of an alternative therapy with conventional drug use and therefore may not volunteer such information when queried about prior medication history. Also, clients may not volunteer such information because of embarrassment or belief that the veterinarian will not approve of such therapy. Therefore it is important to specifically question clients regarding use of natural products. An added complication is that, even with a history of exposure and a product package, the animal may have been exposed to adulterating or contaminating agents that are not listed on the package label.

Clinical pathologic or postmortem findings are rarely specific for intoxication from natural products but will assist in determining affected organ systems and thus will help formulate a differential list. It may be possible to detect specific herbal constituents in biologic specimens. For example, pulegone was detected in tissues from a dog intoxicated by pennyroyal oil (Sudekum et al., 1992). Currently however, analyses for organic natural products

Table 34-3

Drug Dosages for Treatment of Intoxications

Agent	Indication	Dosage
Activated charcoal	Adsorption of toxins	Loading dose of 1-2 g/kg. If multiple doses are given, follow with 0.25-0.5 g/kg q1-6h. Some preparations of activated charcoal contain a cathartic.
Syrup of ipecac	Emesis	Dogs: 1-2 ml/kg PO Cats: 3.3 ml/kg PO diluted 50:50 with water
3% hydrogen peroxide	Emesis	1-2 ml/kg PO; if emesis does not occur, may repeat once more
Apomorphine	Emesis	Do not use in cats. Dogs: 0.03 mg/kg IV or 0.04 mg/kg IM May also place 0.25- to 1.6-mg tablet in the conjunctival sac and dissolve with an ophthalmic irrigating solution. When emesis begins, thoroughly flush remaining material from the sac.
Sodium bicarbonate	Urine alkalinization	1 to 2 mEq/kg administered q3-4h to achieve a urine pH of 7.0 or greater
Digoxin Fab fragments	Cardiac glycosides (plants such as <i>Digitalis</i> , <i>Nerium</i> spp. and <i>Bufo</i> spp. toads)	Dosing is empiric. In humans it is suggested that 1.7 ml (of Digibind) be administered IV per milliliter of digoxin ingested. If dose is unknown, then 400 mg Digibind is given IV. Digibind is given over 30 minutes unless cardiac arrest is imminent, in which case a bolus is given. Monitor for anaphylaxis and hypokalemia.
Cimetidine	Gastric protection (H ₂ blocker)	5-10 mg/kg IV or PO q8h
Sucralfate	Gastrointestinal protection	Small dogs: 0.5 g q8h Large dogs: 1 g q8h
Omeprazole	Treatment and prevention of ulcers	Cats: not recommended Dogs: 20 mg/dog q24h (or 0.7 mg/kg, q24h, PO) [†]
Diazepam	Antiseizure	Dogs: 0.5-2 mg/kg IV or 1 mg/kg rectally ² Cats: 0.5 mg/kg IV or 1 mg/kg rectally
Lidocaine	Premature ventricular contractions	Loading dose of 1-2 mg/kg IV followed by maintenance IV drip of 40-60 mg/kg/min infusion rate to effect Should not be used in cats*
Metoprolol	Tachyarrhythmias	0.1-0.3 mg/kg TID
Misoprostol	GI protection	Dogs: 2-5 mcg/kg q6-8h, PO

Data from Poppenga, 2004 unless otherwise noted.

GI, Gastrointestinal; IM, intramuscularly; IV, intravenously; PO, Orally.

*Carson, 2001.

[†]From Papich MG: *Saunders handbook of veterinary drugs*, Philadelphia, 2002, Saunders, pp 352, 376.

in tissues are not widely available, although analytic methods may improve as their use continues to increase.

TREATMENT OF HERBAL INTOXICATION

The adage “treat the patient and not the poison” is appropriate in most suspected poisonings caused by herbal preparations. Treatment consists of decontamination followed by general supportive care. Indications and contraindications for decontamination procedures should be followed (Poppenga, 2004). Inducing emesis is contraindicated when there is high risk of aspiration (the patient is unconscious or there is neurologic depression) or the patient is having or is likely to have a seizure.

Generally dermal preparations can be removed by washing with a mild soap or detergent. Care should be exercised that the personnel performing this do not themselves become contaminated. Gloves, aprons, and good ventilation are necessary. It is also important to avoid hypothermia in the patient. Supportive care is based on the clinical signs exhibited by the patient. Body temperature, status of the major organ systems, hydration, acid-base balance, urine output, neurologic status, and cardiac function require regular monitoring and evaluation.

In rare cases an antidote might be available (e.g., digoxin Fab fragments for cardiac glycosides). There are also specific considerations for several botanical agents. Intoxication with salicylates frequently results in acidosis. Urinary alkalization using sodium bicarbonate may increase the elimination by trapping the ionized salicylate molecules in the urine. It is also important to protect the gastrointestinal tract against the ulcerogenic potential of the salicylates. Treatment may include a protectant such as sucralfate, a histamine H₂-receptor antagonist (cimetidine, ranitidine or famotidine), a proton pump inhibitor (omeprazole), and misoprostol (a PGE₁ analog).

In cases of poisoning from caffeine/guarana, ephedra, *Citrus aurantium*, and other materials causing CNS stimulation, the animal should be monitored for hyperthermia, dehydration, acidosis, cardiac arrhythmias, and seizures. Along with decontamination, fluid therapy increases urinary excretion and helps to correct electrolyte imbalances. Frequent premature ventricular contractions should be treated with lidocaine (without epinephrine). Tachyarrhythmias may require the use of a β -blocker. It must be remembered that β -blockers may also mask the early signs of shock. Drug dosages are summarized in Table 34-3.

CHAPTER 35

Aflatoxicosis in Dogs

KARYN BISCHOFF, *Ithaca, New York*
TAM GARLAND, *Washington, DC*

Aflatoxicosis in dogs was first described as *hepatitis X* in 1952. The disease was experimentally reproduced in 1955 using contaminated feed and again in 1966 using purified aflatoxin B₁. Moldy corn poisoning of swine and turkey X disease were reported in the 1940s. Turkey X disease was linked to aflatoxin in 1961.

Aflatoxins are a group of related compounds produced as secondary metabolites of various fungi, including *Aspergillus parasiticus*, *A. flavus*, *A. nomius*, and some *Penicillium* spp. Aflatoxins are not produced by all strains of these fungi. The most common aflatoxins in grains are named, in part, for their fluorescent color: aflatoxins B₁ and B₂ fluoresce blue; and aflatoxins G₁ and G₂ fluoresce green. Aflatoxin B₁ is the most common and most toxicologically potent of the aflatoxins.

High-energy agricultural crops are most often affected. Corn, peanuts, and cottonseed are frequently implicated; but rice, wheat, oats, sweet potatoes, potatoes, barley, millet, sesame, sorghum, cacao beans, almonds, soy, coconut, safflower, sunflower, palm kernel, cassava, cowpeas, peas, and various spices have been affected. Mold may grow on crops in the field or during storage. Factors that influence mold growth include temperature, humidity, drought stress, insect damage, and handling techniques.

Ingestion of homemade pet foods, moldy garbage, and improperly stored dog foods all have been implicated in aflatoxicosis.

Commercial grain is screened routinely for aflatoxins, but sampling error has been implicated in contamination of commercial dog food. Uneven distribution of mold growth within the grain (by analogy, one moldy orange in a large bag of fruit or blue veins in a block of blue cheese) increases the risk of sampling error. A simple black light at 366nm induces fluorescence of kojic acid—a chemical also produced by many aflatoxin-producing fungi. Kojic acid fluoresces blue-green. Its presence neither confirms nor eliminates the presence of aflatoxins. More sensitive analyses use enzyme-linked immunosorbent assays, high-performance liquid chromatography (HPLC), and liquid chromatography/mass spectrometry. HPLC is both more sensitive and more specific. Many pet food companies currently sample each lot of grain before using it in food production and then sample batches of pet food after production to minimize the problem of sampling error.

TOXICITY

Dogs and cats are considered very sensitive to aflatoxin (Newbern and Butler, 1969). The oral median lethal dose

(LD₅₀) for aflatoxins in dogs has ranged from 0.5 to 1.8 mg/kg. It has been difficult to determine the total dose of aflatoxin received in field cases when the amount ingested and period of exposure may not be available. Although dog foods containing as low as 60ppb of aflatoxin have been implicated in aflatoxicosis cases, it is rarely possible to know the actual aflatoxin exposure from food consumed before presentation. The experimental oral LD₅₀ for aflatoxin in cats is 0.55mg/kg. No clinical cases of aflatoxicosis have been reported in cats.

Factors such as dose received, genetic predisposition, and concurrent disease may influence the course of aflatoxin poisoning. Generally younger animals, particularly males, may be more susceptible. Aflatoxin-related deaths in pups sucking a clinically healthy dam have been reported (Garland and Reagor, 2007). Pregnant and whelping bitches may be more susceptible to aflatoxicosis. Early castration decreases mortality in males of some species (Meerdink, 2004). Low dietary protein may enhance hepatocyte damage, whereas nutritional antioxidants, vitamin A, and carotene may decrease it.

TOXICOKINETICS

Aflatoxins are highly lipophilic and are absorbed rapidly and almost completely in the duodenum. Aflatoxins enter the portal circulation and are highly protein bound in blood. The unbound fraction is distributed to the tissues, with the highest concentration occurring in the liver.

The liver is the primary metabolic site for aflatoxins. Sites of secondary metabolic interest include the liver, kidneys, and small intestine. Phase I metabolism of aflatoxin B₁ by cytochrome P-450 enzymes produces the reactive intermediate aflatoxin B₁ 8,9-epoxide. Some aflatoxin B₁ is metabolized to aflatoxin M. During phase II metabolism aflatoxin B₁ 8,9-epoxide is conjugated to glutathione in a reaction catalyzed by glutathione S-transferase.

Metabolites of aflatoxin are excreted in both urine and bile. Dogs excrete primarily aflatoxin M₁ in the urine. More than 90% of aflatoxin metabolites are excreted in the urine within the first 12 hours after dosing in the dog, and urine aflatoxin is below detectable levels within 48 hours. Conjugated aflatoxin is excreted predominantly in the bile. Approximately 1% of a dose of aflatoxin is excreted as aflatoxin M₁ in the milk in dairy cattle.

MECHANISM OF ACTION

Phase I metabolism of aflatoxin B₁ produces the highly reactive electrophile aflatoxin B₁ 8,9-epoxide, which binds readily to other molecules within the cell, including nucleic acids, proteins, and other constituents of subcellular organelles. Formation of deoxyribonucleic acid (DNA) adducts modifies the DNA template; thus binding of DNA polymerase may be altered, which in turn affects cellular replication. Binding to ribosomal translocase affects protein production. These changes may lead to necrosis of hepatocytes and other metabolically active cells such as renal tubular epithelium. Coagulopathy may result from decreased prothrombin and fibrinogen production. Excretion kinetics of adducts is slower than the parent compound and the aforementioned metabolites.

Aflatoxin is a known carcinogen in rats, ferrets, ducks, trout, swine, sheep, and rats. *It is not known to be carcinogenic in dogs.* Aflatoxins are classified by the International Agency for Research on Cancer as class I human carcinogens. Hepatocellular carcinoma has been associated with chronic aflatoxin exposure and concurrent infection with hepatitis B virus.

CLINICAL SIGNS

Although aflatoxicosis is usually caused by prolonged exposure to contaminated feed, the presentation in small animals is usually acute. Dogs in recent cases involving contaminated commercial dog foods may have been ingesting the foods for weeks or months before becoming clinically ill. For example, adulterated pet food may have entered the market in October, but the first reported cases were not observed until December. Some dogs did not become symptomatic until up to 3 weeks after the diet was changed.

Clinical signs of aflatoxicosis in dogs usually occur within a few days of death but may be protracted for up to 2 weeks. If the concentration of aflatoxin is very high, this is usual; but animals can, and do, survive when the concentration is low or exposure is limited. Experimentally poisoned cats that died of aflatoxicosis survived only a few days after the onset of clinical signs. Conversely, some cats have been known to survive after clinical signs of aflatoxicosis following exposure to adulterated food.

The most commonly reported early clinical signs of aflatoxicosis in dogs include feed refusal or anorexia, weakness and obtundation, vomiting, and diarrhea. A few animals may die unexpectedly without showing clinical signs. Later in the course of the disease, dogs become icteric. Bilirubinuria was prominent in recent cases. Evidence of coagulopathy may include melena or frank blood in the feces, hematemesis, petechial hemorrhages, and epistaxis.

DIAGNOSIS

The primary differential diagnosis for dogs in recent food contamination-related cases of aflatoxicosis was leptospirosis, as was reported by Stenske and colleagues (2006). Other differential diagnoses that have been considered include parvovirus and anticoagulant rodenticide toxicosis based on the severe gastrointestinal hemorrhage and a variety of hepatotoxic agents, including acetaminophen; microcystin from cyanobacteria; amanitine from mushrooms; and toxins associated with cycad palms, phosphine, and iron.

Diagnosis of aflatoxicosis is often based on history, clinical signs, clinical pathology findings and postmortem changes. Laboratory testing of dog food or other implicated material may be helpful in confirming the diagnosis, but sometimes this material is no longer available. Often all of the contaminated food has been consumed by the time the animal presents to the veterinarian. During a recent dog food contamination incident, three groups of dogs with similar dietary histories and clinical signs were identified by a veterinarian. Dog food was submitted to the laboratory from each of the three households, but

only one sample contained aflatoxin in toxicologically significant concentrations. If the dog food bags or codes from the bags are maintained, it is possible to learn what lot of food may have been contaminated.

Some laboratories test for aflatoxin M_1 in the urine, but urinary excretion is very rapid in dogs. There has been some success with testing serum or liver for aflatoxin, but, again because of the rapid metabolism and excretion of aflatoxin, we have found these tests to be of limited usefulness.

Clinical Chemistry

Complete blood count, serum chemistry, including bile acids, and urinalysis have been recommended to support the diagnosis of aflatoxin poisoning and rule out other causes of liver failure. Total bilirubin is increased in aflatoxicosis. Changes in hepatic enzyme concentrations are variable. Serum alanine aminotransferase was elevated consistently in one report and may increase progressively (Garland and Reagor, 2007). Other liver enzymes, including aspartate aminotransferase, alanine phosphatase, and γ -glutamyltransferase (GGT) may be elevated. Elevated GGT is high on the scale but when it was exceedingly high, it was more often an indication of undiagnosed Cushing's disease.

Other liver function tests have been used to support the diagnosis of aflatoxicosis. Serum albumin is often decreased, and prothrombin time is often increased. Serum protein C, antithrombin III, and cholesterol are often decreased in aflatoxicosis.

Postmortem Findings

Necropsy is helpful in confirming the diagnosis of aflatoxicosis and ruling out other conditions. Common gross pathology findings include icterus, hepatomegaly that may be mild, ascites, gastrointestinal hemorrhage, and multifocal petechia and ecchymosis. Pigmentary nephrosis has been reported.

The primary histologic changes of canine aflatoxicosis are associated with the liver, although necrosis of the proximal convoluted renal tubules has been reported (Hooser and Talcott, 2006). Liver lesions associated with acute aflatoxicosis include fatty degeneration of hepatocytes, which may contain one or many lipid vacuoles. Centrilobular necrosis and canalicular cholestasis are commonly reported. Inflammation is mild.

Dogs with subacute toxicosis still have hepatocytic fatty degeneration, canalicular cholestasis, and multifocal-to-locally extensive hepatic necrosis that may be associated with neutrophilic inflammation and hepatocyte regeneration. Fibrosis becomes more prominent, with bridging of portal triads and proliferation of bile ductules. The central vein may become obscured and replaced with dilated sinusoids. Chronic aflatoxicosis is characterized by less fatty degeneration of hepatocytes but marked disruption of the normal hepatic architecture by fibrosis. Regenerative nodules may be evident grossly.

Hepatic lesions reported in cats with aflatoxicosis are somewhat different. Experimentally affected cats had

hepatomegaly with petechiation. Hepatocytes contained mostly glycogen with minimal lipid. There was bile duct hyperplasia in cats that had clinical signs for more than 72 hours before death.

MANAGEMENT

The prognosis for small animals with clinical signs of aflatoxicosis is guarded. Animals with severe clinical signs often respond poorly to treatment, although early intervention may improve the chances of survival.

As with most other conditions, patient assessment and stabilization are the first steps in management of aflatoxicosis. Toxin exposure should be limited. This may mean removing contaminated food after chronic ingestion and replacing it with a diet containing high-quality protein or giving activated charcoal orally for a recent high-dose exposure such as moldy garbage.

Supportive care includes correcting hydration and electrolyte imbalances with intravenous fluids. Vitamins B and K_1 and dextrose may be added to fluids. Vitamin K_1 therapy decreased clinical coagulopathy after 72 hours of therapy in one clinical case (Garland and Reagor, 2007). Parenteral nutrition may be needed in animals with severe gastroenteric signs. Sucralfate and famotidine have been used to treat these animals. Plasma transfusions have been used to improve clotting profiles.

Liver protectants such as extracts of milk thistle (*Silybum marianum*) have been used clinically and experimentally to treat aflatoxicosis. Silymarin is a mix of flavonolignans from milk thistle, including silybin. When given to chickens fed a diet containing aflatoxin B_1 , changes in liver enzyme profiles and histologic lesions were decreased compared to controls. Various mechanisms of action for silybin have been proposed, such as inhibition of phase I metabolism of aflatoxin B_1 , thus decreasing epoxide production. Although milk thistle products are believed to be liver supportive, when combined with S-adenosylmethionine (SAM-e) in the face of canine chronic aflatoxicosis presenting acutely, these products may prevent the aflatoxin adducts from forming, thus preventing the aflatoxin from leaving the body. (SAM-e) has also been used clinically as a hepatoprotectant in the treatment of aflatoxicosis (Stenske et al., 2006). Sulfhydryl groups on SAM-e may bind aflatoxin B_1 8,9-epoxide.

N-acetylcysteine may be given parenterally and has been used in severely intoxicated dogs. N-acetylcysteine is known to increase cytosolic and mitochondrial glutathione and may act directly as a free-radical scavenger. Experimentally N-acetylcysteine has been shown to enhance elimination of aflatoxin B_1 and prevent liver damage in poultry.

The antischistosomal drug oltipraz has been used to treat aflatoxicosis in humans and experimental animals. Oltipraz inhibits phase I enzymes, CYP1A2 in particular, that metabolize aflatoxin B_1 to the epoxide form. It also induces phase II enzymes, including glutathione S-transferase, to facilitate conjugation of aflatoxin B_1 8,9-epoxide. This drug protects against hepatocarcinogenesis in rats. Oltipraz has not been used in veterinary medicine to our knowledge.

CHAPTER 36

Nephrotoxics

WILSON K. RUMBEIHA, *East Lansing, Michigan*
MICHAEL J. MURPHY, *St. Paul, Minnesota*

The kidney is a frequent target for toxic chemicals (Box 36-1). The recent pet food recall associated renal damage has prompted further consideration of nephrotoxicity in dogs and cats. This chapter provides an overview of the more common nephrotoxics and includes diagnostic considerations for nephrotoxicosis in veterinary patients at the clinic or at the time of post-mortem evaluation. Issues related to pet food safety are addressed in Chapter 37.

PATHOPHYSIOLOGIC CONSIDERATIONS

Renal failure is common, and only a small percent of cases of renal insufficiency are the result of chemical toxins. The kidney constitutes only 1% of body weight in most mammals but receives about 25% of total cardiac output. This high cardiac output exposes the kidney to many substances foreign to the body, including food additives and drugs (i.e., xenobiotics). These chemicals often reach relatively high concentrations in the renal ultrafiltrate. In many instances a high concentration of xenobiotics is associated with nephrotoxicity, but other factors may also play a role.

The kidneys also conduct substantial metabolism of endogenous and exogenous chemicals. Bioactivation of some chemicals can lead to nephrotoxicity, although metabolism of most chemicals leads to detoxification.

Animals may be predisposed to nephrotoxicity. Young and geriatric animals generally are believed to be more susceptible to the nephrotoxic effects of xenobiotics. Young animals may not have fully developed detoxifying enzyme systems, and these systems may be diminished in geriatric animals. Malnutrition, dehydration, preexisting renal conditions, and concurrent exposure to multiple nephrotoxins are some of the factors that may influence the potential for nephrotoxicity.

Causes of acute renal failure in dogs and cats generally can be classified as hemodynamic-related, infectious, or toxic. Toxin-induced acute renal failure is commonly encountered in small animals. Younger animals are the most frequently involved. In dogs the most common causes of nephrotoxicosis are ethylene glycol (EG), nonsteroidal antiinflammatory drugs, cholecalciferol (CCF), and aminoglycoside antibiotics. In cats the most common causes of nephrotoxicity are EG, CCF, and lilies. An expanded list of known nephrotoxins is

Box 36-1

Known Nephrotoxins and Other Causes in the Differential Diagnosis of Acute and Chronic Renal Failure in Dogs and Cats

Household Products and Pesticides

- Cholecalciferol (see text)
- Sodium fluoride, superphosphate fertilizer
- Rodenticides (e.g., phosphorus, thallium)
- Herbicides (e.g., paraquat)

Industrial Compounds

- Ethylene glycol (see text)
- Chlorinated hydrocarbons (e.g., carbon tetrachloride, chloroform, hexachlorobutadiene)

Heavy Metals

- Mercury, cadmium, lead, arsenic, chromium

Pharmaceuticals, Diagnostic Aids, and Anesthetics

- Aminoglycoside antibiotics (see text)
- Cephalosporins (e.g., cephaloridine, cefazolin, cephalothin)
- Polymyxins
- Sulfonamides (e.g., sulfapyridine, sulfathiazole, sulfadiazine)
- Amphotericin B
- Nonsteroidal antiinflammatory drugs (see text)
- Lithium
- Phosphorus-containing urinary acidifiers
- Cyclosporine
- Antineoplastics (e.g., methotrexate, cisplatin)
- Methoxyflurane
- Chelating agents (e.g., D-penicillamine, ethylenediaminetetraacetic acid [EDTA])
- Radiologic contrast media
- Gold salts
- Diuretics (e.g., thiazides, furosemide)
- Vitamin D₃ analog (psoriasis medications)

Natural Toxins

- Easter lily (*Lilium longiflorum*; see text)
- Mycotoxins (e.g., ochratoxin A, citrinin)
- Snake venom
- Mushrooms (e.g., amatoxins)

Ischemic Renal Injury

- Severe volume depletion
- Hemolytic compounds (e.g., zinc toxicosis, acetaminophen toxicosis in cats)
- Thromboembolism of renal arteries in cats

Infectious Conditions

- Acute nephritis (e.g., leptospirosis) or pyelonephritis
- Chronic tubulointerstitial nephritis

Primary Renal Diseases

- Chronic renal disease (idiopathic)
- Amyloidosis
- Familial renal disease

Obstructive Uropathy

- Melamine cyanurate crystals

Ruptured Urinary Conduit

presented in Box 36-1. Only the most common causes of nephrotoxicosis are discussed here, with additional comments directed to the recent pet food-related toxicosis.

ETHYLENE GLYCOL AND DIETHYLENE GLYCOL

EG is a sweet-tasting liquid that is widely used as a solvent in several commercial products such as antifreeze, paints, and polishes. Antifreeze is the most common source of EG exposure in pets. Commercial antifreeze contains about 50% to 95% EG. EG toxicosis is reported all year round but is more prevalent in late fall and early spring.

Toxicosis most commonly occurs within hours of ingestion. EG is rapidly absorbed from the gastrointestinal tract, with peak plasma concentrations occurring about 2 to 3 hours after ingestion. The plasma half-life of EG in small animals is about 3 hours; thus about eight elimination half-lives occur in a day. Diethylene glycol (DEG) is also a widely used organic solvent in commercial products. Antifreeze is the most common source of EG exposure in pets.

EG is metabolized predominantly in the liver. It is metabolized from EG to glycoaldehyde by alcohol dehydrogenase. Glycoaldehyde is metabolized to glyoxalate by aldehyde dehydrogenase. Glyoxalate is finally converted to oxalate, glycine, and formate. The conversion of EG to glycoaldehyde and of glycoaldehyde to glycolate requires nicotinamide adenine dinucleotide (NAD) as a cofactor. Lactate dehydrogenase and glycolic acid oxidase catalyze the conversion of glycolate to glyoxylate. The conversion of EG to glycoaldehyde and of glycolate to glyoxalate are the rate-limiting steps in the metabolism of EG. EG itself is mildly toxic, but its metabolite products, especially glycoaldehyde, glyoxalate, and oxalate, are potentially lethal; thus treatment is aimed at preventing this metabolism.

Toxicity and Signs

Cats are more sensitive to EG toxicity than dogs. The minimum lethal dose of undiluted EG is 1.4 ml/kg in cats and 4.4 ml/kg in dogs. The clinical presentation of EG toxicosis in dogs and cats is often divided into three phases. The first phase generally is 0.5 to 8 hours after ingestion of a toxic dose. The predominant clinical signs in phase 1 are vomiting, depression, and ataxia (an almost "drunken" appearance). These signs are attributed to EG and glycoaldehyde. The latter reaches a peak plasma concentration 6 to 12 hours after EG ingestion. The second phase is generally 8 to 24 hours after ingestion. The predominant clinical signs in phase 2 are depression, anorexia, tachycardia, and pulmonary congestion. If the animal survives these two phases, the third phase begins about 25 to 72 hours after ingestion. The predominant signs during the third phase include vomiting, anuria or oliguria, and uremia, reflecting acute renal failure. Neurologic signs, including seizures, may be observed in some severe cases of intoxication. Laboratory tests are altered during these phases.

An increased anion gap, hyperosmolality, elevated blood urea nitrogen (BUN) and creatinine, hypocalcemia,

isosthenuria, and calcium oxalate monohydrate crystals are the biochemical hallmarks of EG toxicosis in small animals. Glycolic and lactic acids are the main causes of acidosis in EG toxicosis. Lactic acid formation is favored by the increase in the ratio of NADH to NAD, which drives the lactate dehydrogenase reaction. Acidosis can be detected as early as 3 to 4 hours after EG ingestion. Acute renal failure is the consequence of the direct toxic effects of EG metabolism on renal epithelial cells and on the tubular obstructive effects of calcium oxalate crystals. Hyperechoic renal cortices may be evident on ultrasound examination of the kidneys. Bladder size may be small, indicating reduced urine formation.

Treatment of Ethylene Glycol Toxicosis

Treatment of EG toxicosis is most successful if initiated within 12 hours of ingestion (also see Chapters 24 and 29). Gastric decontamination should be initiated by inducing emesis, followed by administration of activated charcoal, provided the patient is presented within 4 to 6 hours of ingestion. Previously intravenous ethanol was the treatment of choice for EG toxicosis, but with approval of 4-methylpyrazole (4-MP) for EG toxicosis in dogs the situation has changed. However, ethanol is still the drug of choice for cats. Ethanol is a preferred substrate of alcohol dehydrogenase; thus it is used to inhibit EG metabolism. However, ethanol is normally of little use if the patient is presented more than 12 hours after ingestion. A 20% ethanol solution is given at 5.5 ml/kg intravenously every 4 hours for 24 hours or in a constant-rate infusion of 1.4 ml/kg/hour for dogs or 1.25 ml/kg/hour for cats. Maintaining ethanol therapy for up to 72 hours normally ensures complete EG elimination. The benefit of ethanol treatment has been questioned, especially in high-exposure situations and comatose animals.

Currently other alcohol dehydrogenase inhibitors may be used to inhibit conversion of EG. The drug 4-MP or Fomepizole (Orphan Medical) is approved for use in dogs (Kirk and Bonagura, 1995). The first dose is given as a 5% solution at 20 ml/kg intravenously. The second dose is given at 15 mg/kg 12 to 24 hours after the first dose. The third dose, if necessary, is given at 5 mg/kg 36 hours after the first one. Unfortunately 4-MP is not recommended in cats, partly because of poor efficacy in this species when using canine doses and the need to administer the drug almost concurrently with ingestion of EG.

Hemodialysis is a referral option in some areas and may be beneficial if started up to 24 hours after EG ingestion. However, dialysis is most effective when initiated within 3 to 4 hours of exposure. Further studies are needed to determine if hemodialysis removes the more toxic metabolites of EG, the time frame over which this therapy is beneficial, and whether or not 4-MP can be used in conjunction with hemodialysis.

Because most patients are presented for treatment late in the course of the disease, the mortality rate of EG toxicosis is higher than 70%. Treatment procedures for EG-induced nephrotoxicosis are summarized in Box 36-2 and Chapter 191.

DEG is also rapidly absorbed from the gut, with peak plasma concentrations reached in 1 to 2 hours.

Box 36-2

Summary of General and Supportive Treatment of Toxic-Induced Acute Renal Failure

Keep the Patient Alive

If Presented Less than 6 hours After Ingestion

- Emesis
Apomorphine hydrochloride, 0.02-0.04 mg/kg IV or IM (if available)
Syrup of ipecac, 2-6 ml PO
or
3% hydrogen peroxide, 5 ml/dog or cat
- Activated charcoal
Acta-Char, 1-4 g/kg
or
Charcodote, 6-12 ml/kg
- Cathartics
Mineral oil, 10-50 ml/dog, 10-25 ml/cat q12h PO
or
Sodium sulfate, 1 g/kg

Supportive Treatment

- Hyperkalemia and acidosis
Sodium bicarbonate, 10 mg/kg q8-12h PO or BW (kg) \times 0.3 \times base deficit
or
(20 – TCO₂) in mEq; half of this dose is given slowly IV in 15-30 min
- Fluid therapy
Ideal fluid is 0.9% normal saline, or 2.5% dextrose in 0.45% saline; to enhance urinary excretion of toxin, correct electrolyte imbalances, manage moderate acidosis, dilute waste products normally excreted by the kidneys
- Diuretics to enhance toxin and metabolic waste products excretion
Furosemide (avoid in gentamicin nephrotoxicity), 2-4 mg/kg as needed IV, IM, SC
Mannitol, 1 g/kg of 5%-25% solution IV (avoid in pulmonary edema)
- Antiemetics or H₂ blockers to correct uremia-induced vomiting
Metoclopramide, 0.2-0.5 mg/kg IV, IM, q6-8h
or
Cimetidine, 2.5-5 mg/kg IV q8-12h
- Give proper nutrition: glucose supplementation, low-quantity but high-quality protein
- Peritoneal dialysis or hemodialysis if azotemia is progressive despite fluid therapy

Run Toxicology Tests to Identify and Remove Specific Underlying Causes

- Withdraw offending drug; eliminate sources (e.g., feed); give chelation therapy in cases such as exposure to heavy metals

BW, Body weight; IM, intramuscularly; IV, intravenously; PO, orally; SC, subcutaneously.

It is metabolized in the liver to its sole metabolite, 2-hydroxyethoxyacetic acid. Oxalate is not a metabolite of pure DEG. DEG is excreted in urine as both parent compound and metabolite. Toxicosis of DEG is characterized by renal failure, acidosis, and cardiac irregularities. The diagnosis of DEG nephrotoxicosis is difficult and

can be supported by its presence or that of its metabolite in blood or urine. Ethers of EG such as EG butyl ether, a component of glass cleaners, may also cause oxalate-induced renal failure.

AMINOGLYCOSIDE ANTIBIOTICS

Aminoglycoside antibiotics are the most frequent class of drugs associated with nephrotoxicosis in dogs and cats. Gentamicin, tobramycin, amikacin, kanamycin, and netilmicin are used for the treatment of gram-negative infections but have a narrow therapeutic index and should be used with caution in animals at high risk for nephrotoxicity, especially those suffering from dehydration or receiving diuretic (furosemide) therapy.

Aminoglycosides are not metabolized *in vivo* and, because of their low molecular weights and high water solubility, are excreted almost exclusively through the urine. *In vivo* these antibiotics easily ionize to cationic complexes that bind to anionic sites on the epithelial cells of the proximal tubules. Following binding, the drugs are internalized by pinocytosis. Renal cortical concentrations of aminoglycoside antibiotics may exceed plasma concentration by tenfold. In general, the toxicity of aminoglycoside antibiotics correlates positively with the number of ionizable groups on the drug. For example, neomycin with six ionizable groups is extremely nephrotoxic and is not used systemically. Gentamicin, tobramycin, amikacin, kanamycin, and netilmicin all have five ionizable groups and a high potential for renal toxicity when used systemically. Aminoglycoside antibiotics can cause acute tubular necrosis through a variety of mechanisms.

Aminoglycoside-induced renal failure is most commonly iatrogenic in origin. Animals receiving aminoglycoside therapy should be monitored for renal injury with periodic urinalyses (specifically evaluation for protein and casts) and with serial determinations of serum urea nitrogen and creatinine. The mortality rate in monitored animals is low. Clinically affected animals may have polyuria, proteinuria, azotemia, and high urinary N-acetyl-B-D-glucosaminidase activity. Nephrotoxicity often can be prevented by increasing the dosage interval by a factor related to the serum creatinine concentration. For example, if the recommended dosing interval is 8 hours and the serum creatinine concentration is 3 mg/dl, the dosing interval should be extended by 3×8 hours = 24 hours.

The treatment of aminoglycoside-induced nephrotoxicosis consists of withdrawing aminoglycoside therapy and then initiating other nonspecific measures, as summarized in Box 36-2 and Chapter 191.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) have diverse chemical structures but similar pharmacologic effects. These drugs are broadly classified into two groups: the carboxylic acids and the enolic acids. Aspirin, indomethacin, tolmetin, sulindac, naproxen, ibuprofen, and flunixin meglumine belong to the carboxylic

acid group. Phenylbutazone and piroxicam belong to the enolic acid group. Additional classification is based on inhibition of specific enzymes (e.g., COX-1 or COX-2 inhibition).

Many NSAIDs are sold over the counter and are widely available in homes. Because of their wide availability, the accidental ingestion of these medications is encountered commonly in small animal practice. Dogs are more involved frequently than cats with acute toxicosis. Iatrogenic NSAID toxicosis is encountered occasionally, is often chronic, and may be to the result of the higher sensitivity of some animals than others to these drugs. Dehydration, poor renal perfusion (as in heart failure), and concurrent treatment with corticosteroids may increase the likelihood of toxicosis.

The NSAIDs are a diverse group of compounds. In general, NSAIDs are well absorbed orally and predominantly metabolized in the liver. Some NSAIDs such as aspirin require glucuronidation. Cats are especially sensitive to the toxicosis of NSAIDs because they have a reduced glucuronic acid conjugating capacity. Nephrotoxicity is certainly not the only adverse effect of NSAIDs. In particular, hepatopathy and gastrointestinal erosions and ulceration pose serious risks to veterinary patients. Gastric and intestinal toxicity often creates signs of anorexia, vomiting, diarrhea, and anemia. Furthermore, these drugs can enhance bleeding tendencies and, especially in cats, predispose to methemoglobinemia. The nephrotoxic effects of these compounds are discussed in the following paragraphs.

The nephrotoxic and antiinflammatory effects of NSAIDs pertain to the ability of these drugs to inhibit prostaglandin production. Most NSAIDs inhibit cyclooxygenase, the enzyme responsible for conversion of arachidonic acid to endoperoxides. Endoperoxides are intermediates in prostaglandin synthesis. Ibuprofen, mefenamic acid, and indomethacin reversibly inhibit cyclooxygenase, whereas aspirin and phenylbutazone inhibit it irreversibly. Some NSAIDs may block prostaglandin receptors.

Ingestion of large doses of NSAIDs may induce acute renal failure. Chronic exposure to toxic doses of NSAIDs may cause renal papillary necrosis. Dehydrated animals, animals in shock, and those with preexisting renal disease are most vulnerable to NSAID-induced nephrotoxicity. Diagnostic tests of value include a careful history, examination of the stool for melena, urinalysis, tests of renal function, serum biochemistries reflecting liver injury, and a complete blood count.

The treatment of acute NSAID toxicosis should involve gastrointestinal decontamination with emetics and activated charcoal (see Chapter 24), intravenous fluid therapy to correct acidosis and maintain urine output, and other life-support measures as needed (see Box 36-2.) The gastrointestinal tract should be treated for potential ulceration and protected from further injury with drugs such as famotidine, omeprazole, sucralfate, or misoprostol (see Chapter 114). In chronic toxicosis the offending drug should be withdrawn. The prognosis is generally good in acute renal injury but is guarded to poor in chronic exposure situations when renal papillary necrosis has occurred.

CHOLECALCIFEROL

CCF (vitamin D₃) is marketed as a rodenticide as well as a nutritional supplement and a treatment for psoriasis. Toxicosis from this compound is related to disruption of calcium homeostasis. CCF toxicosis should always be considered whenever acute renal failure is observed in pets.

Rat baits containing CCF are sold over the counter as Quintox (Bell Laboratories), Rampage (Motomco Ltd.), Rat-B-Gon (The Ortho Group), and other trade names. Poisoning in pets occurs after accidental or intentional bait ingestion. Ingestion (including licking) of human psoriasis medications that contain synthetic vitamin D, analogs such as calcipotriol and calcipotriene, can lead to vitamin D toxicosis. These creams are dispensed under trade names that include Dovonex (Westwood Squibb Pharmaceutical Corp), Taclonex (Warner-Chilcott Company Inc.), or Psorcutan (Intendis).

Although the median lethal dose (LD₅₀) of CCF in dogs is widely reported to be 43 to 88 mg/kg, the experience in my laboratory is that as little as 10 mg/kg given once orally can be lethal. Normal dogs that ingest as little as 4 to 6 mg/kg of CCF once may become sick. Clinically normal dogs that ingest single doses of 2 mg/kg of CCF may develop serum calcium concentrations greater than 12.5 mg/dl.

CCF is rapidly absorbed after ingestion and then transported to the liver. CCF is stored and then slowly metabolized to 25-hydroxy-vitamin D₃ (25-OH-D₃). Then 25-OH-D₃ is metabolized to calcitriol (1,25-dihydroxyvitamin D₃), the active metabolite of CCF in the kidney. Calcitriol stimulates calcium uptake from the gut. In conjunction with parathyroid hormone, calcitriol mobilizes calcium from bone tissue and conserves calcium by enhancing calcium resorption from distal tubules. It is known that high serum concentrations of 25-OH-D₃ stimulate the 1,25-OH-D₃ receptors and trigger similar events. The combined result of these effects is hypercalcemia and hyperphosphatemia, an important point in the differential diagnosis of hypercalcemia or recent onset. Calcification of soft tissues, especially the kidneys, occurs when the calcium and phosphorous product (in milligrams per deciliter) exceeds 60. Renal calcification starts 12 to 18 hours after ingestion, but peak elevation may not be observed until 48 to 72 hours after CCF exposure, coinciding with elevations in serum BUN and creatinine. Early signs of CCF toxicosis include anorexia, vomiting, melena, and depression.

If there is no known history of ingesting bait or psoriasis cream, the clinical signs of toxicosis may be relatively nonspecific. Signs of hypercalcemia, including polydipsia, polyuria, vomiting, and constitutional illness, may be evident. Isothenuria is typical. Hypercalcemia and hyperphosphatemia should prompt consideration of vitamin D toxicosis, especially if renal function is still normal. However, other causes of hypercalcemia must be considered, including malignancies (lymphoma, perianal adenocarcinoma, parathyroid tumors), renal failure, and hypoadrenocorticism.

Treatment of CCF Toxicosis

Treatment of hypercalcemia related to CCF toxicosis can be challenging (see also Chapter 54). Mortality rate is high

because animals are often presented late in the course of disease after substantial renal injury has already occurred. Nonspecific gastrointestinal tract decontamination procedures should be attempted if the animal is presented within 6 to 8 hours of known ingestion (see Chapter 24). Specific therapy is aimed at lowering blood calcium to 8 to 11 mg/dl with the use of salmon calcitonin or another drug. The recommended dosage of calcitonin is 4 to 6 units subcutaneously every 4 to 6 hours until the calcium stabilizes (at least 3 weeks). Pamidronate disodium given at 1.2 mg/kg by a slow saline infusion over 2 hours has been shown to be an effective *alternative* therapy to calcitonin. Two intravenous infusions of pamidronate given 8 days apart have been shown to reverse hypercalcemia of 16 mg/dl to normal for 28 days. Other biphosphonate drugs have been used successfully for treatment of vitamin D-related toxicosis and hypercalcemias of different etiologies but should only be used after consulting an internal medicine specialist or toxicologist.

Nonspecific treatment (see Box 36-2) is frequently used in conjunction with specific calcium-lowering therapies, including furosemide at 2.5 to 4.5 mg/kg every 8 to 16 hours, prednisone at 2 to 6 mg/kg intravenously, intramuscularly, or orally every 24 hours or until blood calcium concentrations return to normal. Fluid therapy with normal saline (0.9% NaCl) is recommended to enhance urine flow and calcium excretion and to correct dehydration.

TOXIC ORNAMENTAL PLANTS

Ingestion of leaves, flowers, or both of the Easter lily (*Lilium longiflorum*) may cause nephrotoxicity in cats. Lily toxicosis in cats was first reported in 1992 and has subsequently been reproduced experimentally. Shortly after eating leaves or flowers, cats develop signs of gastrointestinal upset and become depressed. Acute renal failure characterized by polyuria, dehydration, proteinuria, and glucosuria may be observed 48 to 96 hours after exposure. The toxic agent and mechanism of toxicity have not been established.

The recommended nonspecific therapy includes gastrointestinal decontamination with the use of emetics, activated charcoal, sodium sulfate, and fluid therapy to correct dehydration (also see Chapter 191). This treatment approach is most likely to be beneficial when performed within 6 hours of plant exposure.

DIAGNOSTIC APPROACH TO SUSPECTED NEPHROTOXICITY

Nephrotoxicosis associated with consumption of pet food is quite rare. Yet several million pouches, cans, and bags of pet food were recalled during the spring of 2007 following calls into Regional Offices of the Food and Drug Administration after reports of possible pet food-related nephrotoxicity. Distal renal tubular degeneration and necrosis with crystals deposition were reported in most dogs and cats ingesting pet foods associated with this recall. At the conclusion of the episode, about 300 cats and dogs died and about an equal number were clinically affected but recovered with treatment. This extensive recall included the United States and Canada.

Diagnostic laboratories and the Food and Drug Administration (FDA) have identified the presence of melamine, ammelide, ammeline, and cyanuric acid in some recalled products. The presence of melamine and its analogs is unprecedented in the feed industry. Experimental studies in cats and pigs have revealed that crystal formation was a result of melamine cyanurate crystals. These crystals caused tubular blockage and distal tubular epithelial necrosis. Aspects of pet food safety are discussed in more detail in Chapter 37. The following discussion considers general concepts of diagnosis in terms of nephrotoxicity.

Critical Issues in Establishing Diagnosis of Food-Related Nephrotoxicity

A fundamental part of medicine is consideration of the differential diagnosis. As can be seen from Box 36-1, the causes of acute renal failure in dogs and cats are extensive. Refinement of a diagnosis usually relies on the history, clinical signs, physical examination, and results of laboratory testing. The goal in toxicology cases is establishing an etiology. Often the facts necessary for such a conclusion are not evident; and morphologic, presumptive, or clinical diagnoses are made.

The nephrotoxins EG, CCF, NSAIDs, aminoglycoside antibiotics, and *Lilium* spp. are further examined here to illustrate the point.

Two tenants of toxicology are exposure and dose response. Pets must be exposed to a toxin for it to cause a toxicosis. Further, they must be exposed to a potentially toxic dose and have the adverse effect previously demonstrated for that toxin before a clinician can reach a conclusion of a toxicosis.

In veterinary patients the history and specific laboratory tests are normally used to determine whether an animal has been exposed to a nephrotoxin. The history is often the less reliable of the two methods. For example, does the owner know if his or her pet was exposed to a potentially toxic dose of a drug (NSAIDs, aminoglycosides) with demonstrated nephrotoxicity? Specifically one might inquire if EG, CCF, NSAIDs, aminoglycosides, or *Lilium* spp. plants are present in or around the home. If so, the next step is to confirm or rule out exposure by specific laboratory testing when available. Tests should identify the parent compound or its metabolites.

Quick screening tests are often used to make treatment decisions, but analytic laboratory tests may be required to confirm an etiologic diagnosis. The availability of such confirmatory tests may be investigated by contacting a veterinary diagnostic laboratory (see www.aavld.org or www.abvt.org). Serum or urine is usually the specimen of choice in live animals. For example, although calcium

oxalate crystals in urine might be present in toxicosis in a dog or cat with renal failure, this finding is nonspecific; so serum, urine glycolic acid, or EG concentrations would better support a diagnosis of EG exposure. Similarly serum concentrations of 25-hydroxycholecalciferol are used to indicate exposure to CCF; serum or urine concentrations of NSAIDs and aminoglycosides may be used for the same purpose.

The clinical signs, physical examination findings, and routine laboratory tests may be instructive. Clinical signs of renal toxicosis often include gastrointestinal upset, central nervous system depression, cardiopulmonary involvement, and acute renal failure, as observed with EG toxicosis. Ultrasound may show renal cortical damage. Involvement of other organ systems may provide diagnostic leads. For example, NSAID toxicosis causes often may include gastrointestinal bleeding and ulceration, acidosis, and mild elevations of hepatic enzymes. Clinical signs of CCF toxicosis include dark bloody feces, oliguria, or polyuria.

Laboratory testing often is required to establish the adverse effects of toxicity. Obviously serum urea nitrogen and creatinine along with urinalysis are used clinically to indicate renal injury. Calcium abnormalities are common with EG and with CCF toxicosis. Values within the normal range for all of these tests would be interpreted as arguing against a diagnosis of nephrotoxicity. Such findings may not exclude exposure to a subtoxic dose of a nephrotoxic chemical.

When a patient dies or is euthanatized, necropsy and histopathology findings can in some instances support an argument of exposure to a toxin. For example, the finding of antifreeze solution, CCF rodenticide bait, drug products, or lily plant parts supports exposure to the respective compounds. The observation of birefringent crystals histologically is very suggestive of EG exposure, but even in this case the findings are not specific. For example, such crystals can occur following exposure to soluble oxalates (*Oxalis* spp. plants). Similarly renal mineralization is compatible with, but not specific for, CCF exposure.

In conclusion, the diagnosis of nephrotoxicity must rely on evidence of exposure to a sufficient quantity of a toxic chemical, clinical or analytic laboratory findings that confirm or strongly suggest toxicosis, and clinical or necropsy findings of compatible illness. These same principles should be applied to the diagnosis of new toxicities, including those implied by the recent pet food recall.

Food Toxicoses in Small Animals

MICHAEL J. MURPHY, *St. Paul, Minnesota*

JULIE CHURCHILL, *St. Paul, Minnesota*

"On March 15, FDA learned that certain pet foods were sickening and killing cats and dogs. FDA found contaminants in vegetable proteins imported into the United States from China and used as ingredients in pet food." (<http://www.fda.gov/oc/opacom/hottopics/petfood.html>)

This announcement marked the beginning of one of the most significant recalls of pet food in the United States and Canada. The chemicals melamine, ammiline, ammilide, and cyanuric acid were identified in pet food within weeks of the initial Food and Drug Administration (FDA) announcement. The presence of these chemicals in pet food was unprecedented and judged to be adulteration.

A number of dogs and cats known to have eaten these foods were also treated for clinical signs associated with a laboratory finding of acute renal failure. Questions related to the disease associated with foods subjected to this recall remain. Certainly the demonstration of nephrotoxicity from any chemical requires consideration of both diagnostic and toxicologic principles.

Since this recall many pet owners have become wary of commercial pet foods. Some are seeking nutritional advice and considering alternative diets such as raw meat diets or home-prepared diets. This chapter is designed to complement the general chapter on "Pet Food Safety" by the late Dr. Phillip Miller (see Section II on Evolve). Herein we consider the pet food recall, commercial pet food regulation, and some issues related to homemade pet food diets. The diagnosis and management of chemical nephrotoxicity is detailed in Chapter 36, and the treatment of acute renal failure outlined in Chapter 191.

PET FOOD RECALL

Many United States pet food companies voluntarily recalled some of their product after the FDA's March 15, 2007 announcement. Investigations by the FDA, veterinary diagnostic laboratories, and the pet food industry led to the identification of melamine and its analogs in some lots of pet food. The presence of melamine in some pet food led the FDA and pet food companies to consider the melamine-containing pet food as adulterated. Consequently several pet food companies voluntarily recalled millions of pounds of potentially adulterated product. The recalls proceeded under established FDA regulations.

The unprecedented adulteration of some pet food with melamine led to the widespread pet food recall.

Since widespread product recalls are not common, a brief summary of the regulatory basis for recalls is presented. "Food," "adulterated," and "recall" all have FDA definitions.

"The term "food" means (1) articles used for food or drink for man or other animals, ... and (3) articles used for components of any such article." 21 United States Code, Section. 321 (f)

Pet food is an article used for food for animals; thus it fits the FDA legal definition of "food." Pet food is comprised of many components. Some of these components may also meet the FDA's legal definition of "food." Wheat gluten is an example of such a component. Some of the recalled pet food was judged to be adulterated.

"A food shall be deemed to be adulterated— ...

(4) if any substance has been added thereto or mixed or packed therewith so as to ... make it appear better or of greater value than it is." 21 United States Code, Section. 342 (b)(4).

Adding a substance to a food component to "make it appear better or of greater value than it is" is commonly referred to as "economic adulteration." One theory proposed is that melamine was added to wheat flour as an economic adulterant.

The economic adulterant theory proposes that melamine was added to wheat flour to increase the measured concentration of protein in the wheat flour to that of wheat gluten. Wheat flour is generally lower in protein than wheat gluten. Generally the protein concentration is calculated by testing the product for its total nitrogen concentration and then multiplying the total nitrogen concentration by 6.25 to determine the total protein concentration. Melamine contains six nitrogen molecules per molecule. Addition of melamine to wheat flour apparently increased the calculated protein concentration from that of flour to that of wheat gluten. Because wheat gluten is purchased in large part based on its protein concentration, the price for wheat gluten is higher than the price for wheat flour. Consequently the addition of melamine to wheat flour made the flour "appear better or of greater value" than the flour would have been without the addition of the melamine, thereby satisfying the definition of adulteration.

The melamine-adulterated wheat flour was used as a component in the manufacture of a number of pet food products. One means of removing an adulterated product from the marketplace is a product recall.

"Recall means a firm's removal or correction of a marketed product that the Food and Drug Administration considers to be in violation of the laws it administers and against which the agency would initiate legal action, e.g., seizure. ..." 21 CFR 7.3 (g)

The company frequently initiates the recall of a marketed product.

"A firm may decide of its own volition and under any circumstances to remove or correct a distributed product. A firm that does so because it believes the product to be violative is requested to notify immediately the appropriate Food and Drug Administration district office listed in § 5.115 of this chapter. ..." 21 CFR 7.46(a)

Many pet food companies chose to recall pet food products that had been distributed and to notify the FDA of their recall. A list of these recalled products was posted on the FDA website at <http://www.accessdata.fda.gov/scripts/petfoodrecall/>.

It should be emphasized that not all adulterated products are poisonous. Adulteration is not equivalent to intoxication. Apparently melamine was an economic adulterant in some finished pet food, and this chemical also was detected in the kidneys and urine of some cats that died of renal failure. However, at the time of this writing, the FDA was not "fully certain that melamine is the causative agent" of the cats' death (FAQ, 2007). Investigations are ongoing regarding links between adulteration, specific toxins, and the clinical consequences of toxicosis.

PET FOOD REGULATION

The pet food recall has given rise to questions of regulation of the pet food industry. The widespread pet food recall demonstrates that considerable regulatory authority over the pet food industry exists. The FDA and American Association of Feed Control Officials (AAFCO) are the two major sources of pet food regulation in the United States.

The FDA administers the Federal Food, Drug, and Cosmetic Act (FFDCA). The FFDCA requires that "pet foods, like human foods, be pure and wholesome, safe to eat, produced under sanitary conditions, contain no harmful substances, and be truthfully labeled." (FAQ, 2007). The FDA also "ensures that the ingredients used in pet food are safe and have an appropriate function in the pet food." The "mineral and vitamin sources, colorings, flavorings, and preservatives may be generally recognized as safe or must have approval as food additives" (FAQ, 2007). For example, the FDA monitors bacteria, mycotoxins, pesticides, and metals in commercial pet food products.

The FDA and many states require the listing of food ingredients on the label. Specifically the FDA requires "proper identification of the product, net quantity statement, name and place of business of the manufacturer or distributor, and a proper listing of all the ingredients in order from most to least, based on weight" (FAQ, 2007).

Most states also have pet food labeling requirements. These state requirements generally are based on AAFCO standards. AAFCO is an association of state and federal officials with the basic goal of providing "a mechanism

for developing and implementing uniform and equitable laws, regulations, standards and enforcement policies for regulating the manufacture, distribution and sale of animal feeds; resulting in safe, effective, and useful feeds" (AAFCO website). Although AAFCO provides nutritional guidelines related to feeds, complaints about a pet food product are generally directed to the state Department of Agriculture or to the FDA. Complaints to the FDA are normally made to the district office consumer complaint coordinator. The contact information for the district offices can be found at: <http://www.fda.gov/opacom/backgrounders/complain.html> (also see Chapter 20).

SOME ISSUES RELEVANT TO HOMEMADE PET FOODS

As with any feed, home-prepared pet diets are also subject to consideration for a number of health and stability factors. Among these are microbial content, aerobic stability, unsafe ingredients, and nutritional imbalances.

Microbial Content

A great many recipes for homemade pet food have been posted on the Internet since the pet food recall. Bacterial contamination is a critically important issue in the preparation of homemade pet foods. Generally speaking, microorganisms may grow in an environment in which the pH is greater than 4.6 and the water activity is greater than 0.85 (21 CFR 113.3[n]). The FDA requires that canned pet foods be processed under regulations to ensure the contents are free of viable microorganisms.

Many microorganisms of concern are found in human foods. These organisms include *Clostridium perfringens*, *Clostridium botulinum*, *Staphylococcus aureus*, *Bacillus cereus*, *Salmonella* spp., *Listeria* spp., *Yersinia* spp., *Aeromonas* spp., *Campylobacter* spp., *Escherichia coli*, *Vibrio* spp., *Enterococcus faecalis*, *Enterobacter cloacae*, and *Klebsiella ozaenae*. Other microorganisms to consider in raw meat include *Neorickettsia* spp., *Toxoplasma gondii*, *Neospora canis*, *Echinococcus* spp., and *Trichinella spiralis*.

The presence of microorganisms in uncooked meat may serve as a primary source of disease in pets. Similarly the growth of microorganisms on food during or after preparation should be considered, particularly if the food is not prepared daily. Disease in dogs from *Clostridium botulinum*, *Escherichia coli* O157:H7, and *Salmonella* spp. in both dogs and cats has been reported (Barsanti, Walser, and Hatheway, 1978; Fenwick, Hertzke, and Cowan, 1995; Chengappa et al., 1993; Stiver et al., 2003).

Feeding raw meat can be dangerous not only to pets but also the people who care for them. Pathogenic bacteria from raw meat can contaminate work surfaces in the kitchen, utensils, dishes, the floor where the dog eats, and food and water bowls. This exposure poses an even greater risk in households with children, the elderly, or immunocompromised individuals.

Aerobic Stability

The aerobic stability of home-prepared food may also be an issue. Antioxidants are added to many prepared

human food and commercial pet food products to reduce oxidative decomposition. Foods demonstrating oxidative decomposition are commonly referred to as *rancid*. Diets high in fat are particularly prone to rancidity, which can include destruction of fat-soluble vitamins. Rancidity and microbial growth are two causes of the “garbage gut” syndrome so often seen by practitioners in dogs and cats that have eaten improperly stored food. A similar situation may occur if home-prepared pet foods are not safely constituted or stored before feeding.

Toxic Human Foods

Many animal owners are unaware of the potential adverse effects of “human foods” on their pets. Although not specifically contaminated or rancid, these foods may contain chemicals or natural substances that are toxic to dogs and cats. For example, some human foods worth avoiding in homemade pet food recipes are *Allium* species (chives, onions, garlic), *Brassica* species (kale, Brussels sprouts), kelp, avocado, methylxanthine-containing products (chocolate), rhubarb, grapes, raisins, macadamia nuts, green potatoes, or tomatoes. A number of herbal products should also be avoided (see Chapters 23 and Chapter 34).

Nutritional Imbalances

Nutritional balance is a pivotal aspect of commercially prepared pet foods. A commercial product labeled as dog or cat “food” is by definition a complete and balanced product for that species and requires a nutritional adequacy statement on the product label. Of course there is no requirement or assurance of nutritional adequacy or nutritional balance in recipes published in books or downloaded from the Internet. The nutrient requirements of dogs and cats have recently been reviewed (NRC, 2006). Energy, carbohydrate and fiber, fat and fatty acid, protein and amino acid, mineral, vitamin, and water requirements of dogs and cats are known (NRC, 2006). Although energy, carbohydrate, fat, and protein may be considered by individuals making pet foods, over time vitamin or mineral imbalances may be difficult to avoid.

Nutritional imbalance is more likely to occur with high-protein diets based on meat or raw meaty bones. For example, calcium deficiencies have been documented to occur in meat diets. Diets with high meat content have very high concentrations of dietary phosphorus and low concentrations of calcium. Although it seems that the bones should offer a rich supply of calcium, larger pieces of bones do not appear to be digested and absorbed efficiently. This may result in nutritional deficiency even though bone is intended to serve as the calcium source. The availability of calcium to the dog is highly variable, depending on the size and amount of bones and the age and health of the animal. For example, if the diet contains a very high amount of ground bone, it could be potentially high in calcium, which can be especially harmful to large-breed puppies. High dietary calcium is also believed to contribute to a number of developmental bone diseases such as hip dysplasia, angular limb deformities, and cartilage abnormalities, including osteochondritis desiccans.

Mineral imbalances have also been associated with anemia, goiter, rickets, and secondary hyperparathyroidism.

Vitamin imbalances may also occur in homemade diets. Homemade diets based on meats using offal or high amounts of liver can result in vitamin A excesses and potential toxicity. Raw-meat diets tend to be high in fat, which can lead to either excessive or deficient absorption of the other fat-soluble vitamins. Vitamin imbalances have been associated with anemia, anorexia, dystrophic mineralization, hyperesthesia, myelin degeneration, osteoporosis, reduced growth, and a number of other diseases. Amino acid deficiencies may also occur in homemade diets.

A number of amino acids are classified as being indispensable or *essential*: 11 for cats and 10 for dogs. These essential amino acids must be supplied in the diet because they cannot be synthesized in the body. Most meat-based diets provide adequate amounts of essential amino acids. However, with the new trend toward vegetarian pet diets and with homemade feline diets, careful attention to the amino acid composition is needed to ensure nutritional adequacy.

Because most nutritional problems do not cause noticeable abnormalities until the nutritional imbalance has been present for many months, the link to diet may be hard to identify. Perhaps the best advice for the client insisting on home-prepared pet diets is the following: Question the credentials and training of those advocating the diets and select a recipe that has been formulated by a board-certified veterinary nutritionist.

These issues associated with pet food safety should encourage veterinarians to record a detailed and accurate diet history in the medical record. It is uncertain if pet food changes made by clients in response to the recall in 2007 will result in an increased prevalence of nutrition-based diseases, but veterinarians should be on the lookout for problems related to bacterial contamination, spoiled or rancid food, human food toxicity, or nutritional imbalances.

Interpretation of Endocrine Diagnostic Test Results for Adrenal and Thyroid Disease

ROBERT J. KEMPPAINEN, *Auburn, Alabama*
ELLEN N. BEHREND, *Auburn, Alabama*

The following questions represent frequent inquiries received by our endocrine diagnostic laboratory. In previous editions of this book (Kemppainen and Zerbe, 1989; Kemppainen and Clark, 1995) protocols and interpretation of common endocrine tests were described. Reference ranges mentioned are used by the Auburn University Endocrine Diagnostic Service. Refer to the Table “Systeme International (SI) Units in Clinical Chemistry” in the Appendices for conversions between SI (e.g., nmol/L) and mass units (e.g., g/100ml).

ADRENOCORTICOTROPIC HORMONE STIMULATION TEST

I am having difficulty locating a source for adrenocorticotrophic hormone (ACTH) gel. What should I do?

We recommend the use of Cortrosyn (synthetic ACTH or cosyntropin, Amphastar Pharmaceuticals, Rancho Cucamonga, CA). Cortrosyn is sold in packs of 10 or as a single vial of 0.25 mg (250 mcg). The dose for dogs is 5 mcg/kg intravenously (IV) (maximal dose, 250 mcg; Kerl et al., 1999); for cats the dose is 125 mcg IV. In dogs and cats a pre-ACTH sample is collected, ACTH is injected, and one post-ACTH sample is collected 1 hour later. Recent work indicates that the 5 mcg/kg dose is equally effective in dogs when given intramuscularly (IM), using the same sampling times (Behrend et al., 2006). Once a Cortrosyn vial is reconstituted, it can be stored in the refrigerator for up to 4 months and reused. We recently tested four ACTH formulations compounded by pharmacies and sold to veterinarians (Kemppainen, Behrend, and Busch, 2005). This study, performed using healthy laboratory dogs, showed that each of these products stimulated serum cortisol to an equivalent extent, as did Cortrosyn when samples were collected at 1 hour after ACTH injection; but values at 2 hours after ACTH varied considerably. Therefore we recommend that users of compounded ACTH products collect two post-ACTH samples (at 1 and 2 hours after ACTH). To our knowledge no studies have yet assessed responses to various forms of compounded ACTH in dogs with adrenal disease, nor have possible variations in responses related to lot-to-lot differences been conducted.

I performed an ACTH stimulation test to evaluate a dog for Addison's disease, and the post-ACTH cortisol value was greater than normal. Could this dog actually have hyperadrenocorticism?

It's unlikely. It is not uncommon to find a mildly-to-moderately elevated post-ACTH cortisol concentration in dogs tested for Addison's disease (in dogs not affected by the disease). Presumably a normal physiologic response to recent (or chronic) stress is the cause of the elevation; thus we consider this response to be indicative of a normal pituitary-adrenal axis. In true cases of Addison's disease, cortisol concentrations both before and after ACTH are usually very low (both less than 10 nmol/L).

Can recent steroid therapy affect the ACTH stimulation test?

Yes, glucocorticoids can affect the results in two ways. First, some glucocorticoids cross-react in the cortisol assay and can be detected as immunoreactive cortisol. In our assay, cross-reacting steroids include hydrocortisone, prednisone, and prednisolone. In general, we recommend waiting at least 12 hours after (oral) administration to allow these drugs to clear. Second, glucocorticoid therapy may suppress the pituitary-adrenal axis, causing reduced cortisol concentrations before and after ACTH administration. The severity and duration of this suppression is related to dose, potency, frequency of use, and chemical form (e.g., repositol versus oral) of the glucocorticoid therapy.

I treated a dog suspected of having Addison's disease with steroids yesterday, and now I want to perform an ACTH stimulation test. Will the results be meaningful?

Yes, they probably will be useful. A single injection (or infusion) of glucocorticoids may lower the cortisol values in the ACTH stimulation test. However, this type of short-term, nonrepositol treatment will only moderately lower the cortisol values (about 25%) relative to the normal range. Most dogs with Addison's disease have very low plasma cortisol concentrations and fail to show any increase in cortisol in response to ACTH.

How do I monitor the efficacy of mitotane therapy?

Periodic ACTH stimulation testing is recommended in all dogs with hyperadrenocorticism treated with mitotane. "Ideal" cortisol concentrations in a dog receiving treatment are between 30 and 150 nmol/L in both pre- and post-ACTH samples. If values are below ideal, mitotane should be discontinued, and the dog rechecked with ACTH stimulation periodically (i.e., about every 2 to 3 weeks at first). Once values rise into the ideal range, maintenance therapy can be instituted. If values are mildly-to-moderately greater than 150 nmol/L (e.g., in the 150- to 300-nmol/L range), one should consider increasing the dose (approximately 25%) if maintenance therapy is being given or continuing daily loading therapy for a few additional days. If values are higher, it is likely that 5 to 7 days of daily mitotane will be necessary to reduce the adrenal cortical mass to the target level. Clinical condition and recurrence of signs must be considered in the choice of therapy.

How long should I wait between performing a dexamethasone suppression test and an ACTH stimulation test?

We suggest waiting at least 48 hours after a low dose of dexamethasone (0.01 to 0.015 mg/kg) and 5 days after a high dose of dexamethasone (0.1 to 1.0 mg/kg). No delay is necessary when performing the combined dexamethasone suppression-ACTH stimulation test (Kempainen and Zerbe, 1989). Dexamethasone suppression tests can be performed the day after ACTH stimulation testing.

DEXAMETHASONE SUPPRESSION TESTING*What form of dexamethasone should I use for a dexamethasone suppression test?*

Dexamethasone in polyethylene glycol or dexamethasone sodium phosphate can be used, but the dose is based on the amount of active dexamethasone in solution. For example, a 4-mg/ml solution of dexamethasone sodium phosphate provides about 3 mg/ml of active dexamethasone. The dexamethasone can be given IV or IM, although we prefer the IV route.

I think I injected the dexamethasone outside the vein. What should I do?

It is best to wait 48 hours (low dose) or 72 hours (high dose) and repeat the test.

The calculated (low) dose of dexamethasone is only 0.03 ml for this poodle. How do I accurately administer such a small volume of dexamethasone?

It is important to administer the correct dose. Dilute the dexamethasone (e.g., make a 1:20 dilution by mixing 0.2 ml of dexamethasone with 3.8 ml of sterile saline or sterile water) so that a reasonable volume is given. (For Azium, a 1:20 dilution will make the solution 0.1 mg/ml.)

Can I use the results of the low-dose dexamethasone suppression test to both diagnose and differentiate hyperadrenocorticism in dogs?

Sometimes the results can strongly indicate a diagnosis of pituitary-dependent hyperadrenocorticism (but never adrenal-dependent hyperadrenocorticism). If the concentration in the 8-hour sample is greater than 30 nmol/L, the results are consistent with hyperadrenocorticism. If in addition the 4-hour postdexamethasone cortisol concentration is less than 30 nmol/L and/or the concentration in the 4- and/or 8-hour sample is less than 50% of the predexamethasone cortisol concentration, pituitary-dependent hyperadrenocorticism is likely.

GENERAL QUESTIONS CONCERNING THE DIAGNOSIS OF HYPERADRENOCORTICISM*Do normal results on an ACTH stimulation test or a low-dose dexamethasone suppression test rule out hyperadrenocorticism? Conversely, do abnormal results definitely diagnose the disease?*

Results of the ACTH stimulation test will be in the normal range in at least 20% of dogs with hyperadrenocorticism, whereas the false-negative rate with the low-dose dexamethasone test is approximately 5%. If results of one test are normal but clinical suspicion for the disease is high, one should consider performing the other screening test. It is important to recognize that each test also has false-positives, particularly when dogs with nonadrenal disease are tested. Interestingly, of the two screening procedures the low-dose dexamethasone suppression test seems more prone to this potential error. About 50% of dogs in one study with nonadrenal illness had abnormal results (inadequate suppression of plasma cortisol) when tested with a low dose of dexamethasone (Kaplan, Peterson, and Kempainen, 1995). None of the dogs in that study had a clinical presentation or signs consistent with hyperadrenocorticism. Assessment of test results in dogs with nonadrenal illness in which a clinical suspicion of hyperadrenocorticism is also present is challenging. The predictive value for hyperadrenocorticism of a positive screening test result increases in direct proportion to the number and severity of clinical signs and biochemical changes typically occurring in the disease.

What is the best test for hyperadrenocorticism in cats?

We recommend the high-dose dexamethasone suppression test, administering the steroid at a dose of 0.1 mg/kg IV and collecting a predexamethasone sample and two samples after dexamethasone administration (at 4 and 8 hours).

How and why should I try to differentiate pituitary- from adrenal-dependent hyperadrenocorticism in dogs?

Unless results of the low-dose dexamethasone suppression test support pituitary-dependent hyperadrenocorticism, a differentiating test is recommended. Results of ACTH stimulation testing cannot differentiate the types. The two endocrine tests for this purpose are the high-dose dexamethasone suppression test (0.1 or 1.0 mg/kg in dogs and 1 mg/kg in cats) and endogenous ACTH measurement. Timing of sample collection in the high-dose-dexamethasone suppression test is the same as for the low-dose test. If cortisol concentrations at 4 and/or

8 hours post dexamethasone suppress (>50% decline from baseline or decline to <30 nmol/L), a diagnosis of pituitary-dependent disease is made. However, in about 15% to 20% of dogs with pituitary-dependent hyperadrenocorticism, cortisol is not suppressed by dexamethasone. Considering that cortisol is not suppressed by dexamethasone in dogs with adrenal-dependent disease, and that pituitary-dependent disease is the most common form, a failure to suppress in response to dexamethasone means that the odds of having either form is about 50%. In other words, failure of cortisol concentrations to suppress in response to high-dose dexamethasone does not mean that a patient has an adrenal tumor. Endogenous ACTH measurement can positively differentiate the forms, since circulating ACTH concentrations are low to nondetectable in adrenal-dependent disease and normal to high in pituitary-dependent disease. Unfortunately there is also a grey zone relative to the interpretation of endogenous ACTH measurements, and values that fall into this range are nondiagnostic. Accurate measurement of ACTH in plasma requires special sample handling (Kemppainen and Clark, 1995). Other means to differentiate hyperadrenocorticism include ultrasonography and other imaging modalities and surgical exploration. It is important to distinguish the forms because of differences in therapy and prognosis. Surgical removal of an adrenal tumor can be curative. If mitotane is used for medical management, the therapeutic approach is different, depending on the type of disease. In general, adrenal-dependent disease requires higher dosages and a longer induction phase (Kintzer and Peterson, 1989). Overall the prognosis varies between the two forms.

What is the value in measuring a urinary cortisol:creatinine ratio (UCCR)?

This test is best used to determine if a dog does *not* have hyperadrenocorticism. Nearly 100% of dogs with spontaneous hyperadrenocorticism have an elevated UCCR. Unfortunately many dogs with an elevated UCCR do not have hyperadrenocorticism. Consequently a high ratio means that hyperadrenocorticism is possible, and a more definitive screening test (ACTH stimulation, low-dose dexamethasone suppression test) is indicated. Therefore a normal UCCR is valuable in ruling out hyperadrenocorticism.

CANINE HYPOTHYROIDISM

What is the value of measuring total thyroxine (T_4)?

Total T_4 can best be used to rule out the diagnosis of hypothyroidism. If the total T_4 is well into the normal reference range (i.e., >25 nmol/L), it is unlikely that the dog is hypothyroid. If the T_4 is less than normal, the dog may or may not be hypothyroid. Numerous nonthyroidal factors such as medications and chronic illness (i.e., euthyroid sick syndrome) can suppress T_4 to less than the normal range (also see Chapter 41 for additional details about thyroid testing).

What is the value of measuring free T_4 ?

Free T_4 (FT_4) is the portion of total T_4 not bound to protein and represents about 0.1% of total T_4 . The pituitary-thyroid axis functions to maintain free, not total, T_4 within a certain range; thus measurement of FT_4 is a better test of thyroid function. Two methods are used to measure FT_4 : analog radioimmunoassay and equilibrium dialysis. Analog radioimmunoassay is less expensive but is not reliable in dogs with euthyroid sick syndrome; it provides no additional diagnostic value over measurement of total T_4 (Nelson et al., 1991). Equilibrium dialysis gives more reliable estimates of true FT_4 concentrations. Measurement of FT_4 can be the initial test for the diagnosis of hypothyroidism, or it can be used in dogs that have been found to have borderline-low total T_4 concentrations. However, it has been demonstrated that nonthyroidal disease and therapy with certain drugs (e.g., phenobarbital, glucocorticoids) are associated with reduced FT_4 , even when measured using the dialysis method (Ferguson and Peterson, 1992; Kantrowitz et al, 1999, 2001). Measurement of FT_4 by dialysis is more effective than total T_4 in distinguishing euthyroidism from hypothyroidism. However, all of the current tests for diagnosing hypothyroidism in dogs can be influenced by nonthyroidal factors.

How would I know if autoantibodies to thyroid hormones are present, and what is their significance?

Autoantibodies are usually suspected when total T_3 or T_4 concentrations are high in a sample from a dog evaluated for hypothyroidism. With procedures used by most diagnostic laboratories, the presence of autoantibodies causes false elevations in the apparent concentration. Total T_3 is most often affected; however, autoantibodies to T_3 are present in less than 1% of samples submitted to our laboratory. The exact clinical and prognostic significance of autoantibodies to thyroid hormones is unknown (Kemppainen and Young, 1992). Presence of autoantibodies to T_4 or T_3 does not mean that a dog is hypothyroid. If autoantibodies are present, it is best to measure FT_4 by equilibrium dialysis and thyroid-stimulating hormone (TSH) to better evaluate thyroid function. If the FT_4 and TSH concentrations are normal, the patient should be scheduled for periodic (every 4 to 6 months) FT_4 determination. If the FT_4 level is low and TSH is elevated, hypothyroidism is likely.

How valuable is measurement of endogenous canine TSH?

In dogs with primary hypothyroidism, TSH concentrations are expected to be elevated because of the loss of negative feedback by thyroid hormones on the pituitary. Since about 95% of canine hypothyroidism is caused by primary thyroid failure (and not deficiency of pituitary TSH), measurement of TSH should be a useful test. Indeed, thyroidectomized dogs had TSH levels approximately 30 times greater than normal (Williams et al., 1996). Data obtained using the assay so far are somewhat discouraging, at least in terms of the test providing an unequivocal diagnosis of the disease. In one study of 62 normal dogs, 3 showed elevated TSH concentrations; and, although 7 of 16 spontaneously hypothyroid dogs had clearly elevated TSH levels, 3 had only marginal increases, and 6 had TSH concentrations within the normal range (Scott-Moncrieff et al., 1998).

Another concern was that 4 of 33 dogs with euthyroid sick syndrome had elevated TSH concentrations. Thus data so far suggest that concentrations of TSH are elevated in most but not all dogs with primary hypothyroidism and that approximately 10% of healthy dogs and dogs with euthyroid sick syndrome have TSH concentrations greater than currently established normal ranges. More commonly it appears that a significant number (approximately 25% to 30%) of hypothyroid dogs have normal TSH concentrations. A sole determination of endogenous TSH concentration should not be used to diagnose hypothyroidism. The test should be used to supplement historical data and clinical examination findings in conjunction with measurement of total or FT_4 concentrations or both. Interestingly, concentrations of TSH appear less affected, compared with total T_4 , total T_3 , and FT_4 concentrations, by nonthyroidal illness in dogs (Kantrowitz et al., 2001).

The total T_4 concentration in a dog suspected of having hypothyroidism is less than normal. How certain can I be that this dog is hypothyroid?

A low total T_4 means that the dog may be hypothyroid; alternatively a nonthyroidal factor could be depressing T_4 , or this dog could simply have a lower than “normal” circulating total T_4 concentration (and be euthyroid). Some options available for evaluating these patients are summarized below:

- FT_4 (dialysis method) and TSH can be measured. These tests are more definitive than total T_4 . This is the best option.
- Total T_4 can be retested in 6 to 8 weeks. If the dog is hypothyroid, the T_4 should continue to decline, and clinical signs should become more profound.
- Trial thyroid hormone replacement therapy can be attempted. The dog should be reevaluated after 5 and 10 weeks of T_4 therapy using objective criteria (e.g., regrowth of hair) to assess recovery. A postpill T_4 level should be evaluated after 5 weeks to ensure that therapeutic and not elevated blood levels of the hormone are present. Trial therapy is complicated by partial responders and the fact that T_4 may have a pharmacologic effect to induce hair growth in some euthyroid dogs. Incorrect diagnosis can consign the owner to providing lifelong therapy; thus the first two options are strongly recommended in preference to the third.

How do I test for hypothyroidism when a dog is on thyroid supplementation?

Trying to confirm a diagnosis of hypothyroidism after thyroid replacement therapy has been initiated can be difficult. Therapy should be withdrawn, and the pituitary-thyroid axis allowed to recover. A total T_4 or better FT_4 by equilibrium dialysis should be measured after 1 month. If the result is borderline, therapy should be withheld for an additional 4 weeks, and the measurement repeated to see if there is continuing recovery. The time needed to allow full recovery of thyroid gland function after chronic suppression by exogenous T_4 is unknown.

FELINE HYPERTHYROIDISM

Does the finding of a normal T_4 level in a cat rule out hyperthyroidism?

No. Cats with early or mild hyperthyroidism may have a T_4 concentration within the upper half of the normal range (i.e., 25 to 50 nmol/L). The T_4 level can fluctuate in and out of the normal range in such cats. Alternatively nonthyroidal factors (illness) can suppress the T_4 level in a hyperthyroid cat into the upper half of the reference range.

If the T_4 level is normal but I am still suspicious of hyperthyroidism, what can I do?

If the T_4 level is less than 25 nmol/L, it is unlikely that the cat is hyperthyroid. If the T_4 level is in the upper normal range (25 to 50 nmol/L), further evaluation is warranted. In sick, older cats with a normal thyroid function, low total T_4 concentrations are typically measured (Peterson and Gamble, 1990). Options to consider in hyperthyroid-suspect cats with T_4 values in the upper normal range follow:

- FT_4 should be measured by equilibrium dialysis (Peterson et al., 2001).
- The total T_4 measurement should be repeated; sometimes T_4 will fluctuate into and out of the normal range in hyperthyroid cats. Alternatively tests such as T_3 suppression or thyrotropin-releasing hormone stimulation can be used.

What is the value of measuring FT_4 in cats suspected of being hyperthyroid?

The rationale of using the FT_4 to diagnose hyperthyroidism in cats is the same as that for using this measurement in dogs—that the concentration of FT_4 is less affected by nonthyroidal factors. In this instance FT_4 should be high in hyperthyroidism. Its use seems most appropriate for cats with mild or early hyperthyroidism or in cats suspected of being hyperthyroid with nonthyroidal illness that have total T_4 concentrations in the upper normal range (see earlier). In one study FT_4 was elevated in 191 of 205 mildly hyperthyroid cats (93%) as compared with finding an elevated total T_4 in 125 of these cats (61%) (Peterson et al., 2001). However, FT_4 may also be elevated in up to 12% of sick, euthyroid cats (Mooney, Little, and Macrae, 1996). To help discriminate between hyperthyroidism and euthyroid sick syndrome in cats, a total T_4 should be measured along with the FT_4 . Hyperthyroid cats tend to have total T_4 concentrations in the upper half of the normal range; whereas sick, euthyroid cats have total T_4 values in the lower half of the normal range, even if they show elevated FT_4 (Mooney et al., 1996).

The total T_4 concentration in a cat I was testing for hyperthyroidism came back less than normal. Is the cat hypothyroid?

It is unlikely. It is most likely that the cat has the euthyroid sick syndrome since hypothyroidism is rare in cats. Measurement of FT_4 will help differentiate hypothyroidism from the euthyroid sick syndrome.

Medical Treatment of Feline Hyperthyroidism*

LAUREN A. TREPANIER, *Madison, Wisconsin*

Hyperthyroidism is the most common endocrine disorder in cats, affecting approximately 2% of all cats presenting to veterinary teaching hospitals. Management options include radioiodine therapy, thyroidectomy, or medical treatment with antithyroid drugs such as methimazole. Radioiodine is considered the treatment of choice for hyperthyroidism based on its high efficacy and relative lack of complications (Table 39-1) (see Chapter 40). However, there are some situations in which methimazole therapy may be preferred over radioiodine. Methimazole is useful before thyroidectomy to normalize serum thyroxine (T_4) concentrations and reduce the risk of tachyarrhythmias during anesthesia. Methimazole, which is reversible, is similarly indicated in cats with renal insufficiency, either for long-term therapy or as a “clinical test” to determine whether serum T_4 can be safely lowered without causing renal decompensation. Practical considerations such as lack of a convenient referral center with a radiation license, client fears about radiation or quarantine, or initial cost to the client may also drive the use of methimazole.

METHIMAZOLE ACTIONS, DOSING, AND EFFICACY

Methimazole blocks thyroid hormone synthesis by inhibiting thyroid peroxidase, the enzyme involved in the oxidation of iodide to iodine, incorporation of iodine into thyroglobulin, and coupling of tyrosine residues to form T_4 and triiodothyronine (T_3). Methimazole does not block the release of preformed thyroid hormone, which explains the delay of 2 to 4 weeks before serum T_4 concentrations fully normalize after beginning treatment in cats. Methimazole does not decrease goiter size; in fact, goiters may become larger over time despite therapy.

Typical starting doses of methimazole range from 1.25 to 2.5 mg per cat twice daily (Table 39-2). More frequent dosing (three times daily) is rarely necessary. Higher doses of 5 mg two to three times daily, used in original cases of cats with relatively high serum T_4 concentrations, are probably not needed for initial therapy of cats with mild-to-moderate hyperthyroidism and could potentially increase the risk of renal decompensation from a rapid fall in serum T_4 . Starting dosages can be titrated upward if there is an inad-

equated initial response to lower doses of methimazole over 2 to 4 weeks. In cats that tolerate methimazole without side effects, efficacy is greater than 90%.

In humans methimazole has a long residence time in the thyroid gland and can exert antithyroid effects for 24 hours or more. Because of this, methimazole can be given once daily in humans with remission rates that are comparable to divided daily dosing. However, when our group studied 40 hyperthyroid cats we found that once-daily dosing (5 mg) was less effective than divided dosing (2.5 mg twice daily), with only 54% of cats achieving a euthyroid state after 2 weeks of once-daily treatment compared to 87% of cats treated with divided dosing (Trepanier et al., 2003). Therefore, unless clients are unable to dose more frequently than once daily, divided twice-daily dosing of methimazole is preferred to maximize efficacy. Dosing less frequently than once daily is unlikely to be effective because serum T_4 concentrations rise to pretreatment hyperthyroid values within 48 hours after discontinuing methimazole.

METHIMAZOLE SIDE EFFECTS

Blood Dyscrasias

Methimazole can lead to neutropenia and/or thrombocytopenia in 3% to 9% of treated cats. Cats with methimazole-induced blood dyscrasias usually recover within a week of drug discontinuation. Continuing methimazole in the face of thrombocytopenia has led to clinically significant hemorrhage, including epistaxis and oral bleeding. Rechallenge with methimazole in cats with neutropenia can lead to a recurrent severe neutropenia within 1 week. Although the mechanisms for these blood dyscrasias in cats have not been established, methimazole-induced neutropenia in humans is associated with an arrest of myeloid progenitors in the bone marrow. Treatment with granulocyte-macrophage colony-stimulating factor has been advocated in human patients, but does not appear to hasten recovery in most people.

Facial Excoriation

Approximately 2% to 3% of cats treated with methimazole develop excoriations of the face and neck, leading to characteristic scabbed lesions in front of the pinnae. Generalized erythema and pruritus may also occur. These excoriations are only partially responsive to glucocorticoids, and drug discontinuation is almost always required.

Table 39-1

Advantages and Disadvantages of Major Therapies for Feline Hyperthyroidism

Treatment	Advantages	Disadvantages
Radioiodine	>90% efficacy Single injection Few side effects (rare dysphagia) Curative	High initial expense Somewhat limited availability Irreversible
Thyroidectomy	≈90% efficacy Curative	High initial expense Anesthetic risks Risk of hypoparathyroidism Risk of recurrent laryngeal nerve damage Irreversible
Methimazole	Low initial expense ≈90% efficacy in cats that do not have side effects Reversible	Daily drug administration Drug side effects

Table 39-2

Drugs Useful in the Medical Management of Hyperthyroidism

Drug	Indications	Dosage	Side effects	Comments
Methimazole	Hyperthyroid cats with azotemia or for clients declining radioiodine	1.25-5 mg per cat twice daily (start at lower end)	GI upset Facial excoriation Blood dyscrasias Hepatopathy	Transdermal route has fewer GI side effects
Carbimazole	Prodrug of methimazole	2.5-5 mg per cat twice daily	GI upset Facial excoriation Blood dyscrasias Hepatopathy	Not recommended in cats intolerant of methimazole
Iopanoic acid or calcium ipodate	Adjunct control of T_3 in cats intolerant of methimazole	100-200 mg per day (empiric)		Inhibits conversion of T_4 to T_3 Effects may be transient
Propylthiouracil	Unclear if useful for cats intolerant of methimazole	25 mg per cat twice daily (empiric)	Hemolytic anemia Thrombocytopenia Bleeding diathesis	
Propranolol	Control of tachyarrhythmias or hyperactivity Adjunct control of T_3 in cats intolerant of full dosages of methimazole	2.5-5 mg per cat three times daily	Bronchoconstriction in cats with prior lower airway disease	Inhibits conversion of T_4 to T_3
Atenolol	Control of tachyarrhythmias or hyperactivity	3.125-6.25 mg per cat twice daily	Sinus bradycardia AV block in susceptible cats	Selective β_1 - blocker
Enalapril or benazepril	Control of hypertension	0.5 mg/kg once or twice daily	Lethargy Inappetence	Potential effect of limiting glomerulosclerosis in cats with renal disease Benazepril does not accumulate in renal failure
Amlodipine	Control of moderate-to-severe hypertension	0.625 mg per cat once daily	Lethargy Inappetence	Drug of choice for severe hypertension

GI, Gastrointestinal; T_3 , triiodothyronine; T_4 , thyroxine.

Pruritus has also been reported in human patients treated with methimazole, but the mechanisms for these reactions have not been explored.

Hepatotoxicity

Increases in serum alkaline phosphatase (SAP) and bilirubin, or alanine aminotransferase (ALT), are observed in approximately 2% of cats treated with methimazole (Peterson, Kintzer, and Hurvitz, 1988); liver biopsy may show hepatic necrosis and degeneration. Liver enzyme elevations are usually reversible over several weeks following drug discontinuation, although nutritional and fluid support may be required. Rechallenge can lead to recurrent hepatopathy, and future drug avoidance is generally recommended. In rodent models methimazole hepatotoxicity is exacerbated by glutathione depletion (Mizutani et al., 1999). The role of glutathione depletion, or supplementation, in methimazole-associated hepatotoxicity in cats has not been evaluated.

Simple Gastrointestinal Upset

Anorexia, vomiting, and lethargy are seen in approximately 10% of cats treated with methimazole. Simple gastrointestinal (GI) upset is most common in the first 4 weeks of treatment and can resolve with a dosage reduction. These signs may be caused in part by direct gastric irritation from the drug, since transdermal administration of methimazole is associated with significantly fewer GI side effects than the oral route (Sartor et al., 2004).

Renal Decompensation

Cats with hyperthyroidism have abnormally high glomerular filtration rates (GFRs), and treating hyperthyroidism by any method leads to decreases in GFR in most hyperthyroid cats. New onset azotemia is observed in 15% to 20% of hyperthyroid cats after normalization of serum T_4 . Although these biochemical changes are generally clinically silent, occasional cats develop signs of illness referable to underlying renal disease. Because methimazole treatment is reversible, it is the preferred approach for initial treatment of hyperthyroid cats with preexisting azotemia to determine whether normalization of serum T_4 will lead to unacceptable renal decompensation.

Coagulation Abnormalities

Methimazole and to a lesser extent propylthiouracil (PTU) inhibit vitamin K-dependent clotting factor activation (γ -carboxylation) and epoxide reductase (necessary for vitamin K recycling, and the same enzyme targeted by warfarin) at high concentrations. In a study of 20 hyperthyroid cats treated with methimazole, there were no significant changes in prothrombin time or activated partial thromboplastin time, but one cat developed a prolonged protein-induced by vitamin K antagonism (PIVKA) clotting time (Randolph et al., 2000). No cats had clinically significant bleeding. This suggests a possible but apparently uncommon "warfarin-like" effect of methimazole in cats. This reaction is rare enough not to warrant routine moni-

toring but should be considered in any cat presenting with hemorrhage that is also being treated with methimazole.

Acquired Myasthenia Gravis

Another apparently rare side effect of methimazole in cats is the development of acquired myasthenia gravis. Neuromuscular weakness, along with antibodies to the acetylcholine receptor, has rarely been reported in cats treated with methimazole. Cats have responded to either drug discontinuation or the addition of prednisone to the methimazole treatment regimen. Although this does not appear to be a side effect of methimazole in humans, hyperthyroidism itself can copresent with myasthenia in humans; in one human patient methimazole therapy was thought to worsen the clinical signs of myasthenia.

CLINICAL MONITORING

Based on the spectrum of possible adverse reactions to methimazole, clinical monitoring at 2 to 3 and 4 to 6 weeks of treatment should include a complete blood count, ALT and SAP, and blood urea nitrogen and creatinine, in addition to serum T_4 . In a cat with an apparent adverse reaction to methimazole, it is important to differentiate simple GI upset (for which a lower dose or a switch to transdermal methimazole may be curative) from blood dyscrasias or hepatopathy, for which methimazole should be discontinued. Therefore this same workup should also be performed if a cat becomes clinically ill during methimazole treatment.

It is also important to measure renal function and T_4 simultaneously during methimazole therapy to determine whether a cat's kidneys can tolerate the level of GFR associated with normal thyroid function. If a cat becomes newly azotemic with clinical signs, the dosage of methimazole can be titrated to maintain the serum T_4 in the high high-normal range, with additional use of drugs to control hypertension and tachyarrhythmias (see Management of Hypertension).

TRANSDERMAL METHIMAZOLE

Methimazole is available through custom compounding pharmacies in a transdermal formulation in pluronic lecithin organogel (PLO). PLO acts as a permeation enhancer to allow drug absorption across the stratum corneum. Although methimazole in PLO has been shown to have poor absorption in cats after a single dose, chronic dosing in hyperthyroid cats is effective in lowering serum T_4 concentrations. Methimazole in PLO is applied to the cat's inner pinna, alternating ears with each dose. Owners wear examination gloves or finger cots during administration and are instructed to remove crusted material with a moistened cotton ball before the next dose.

Transdermal methimazole had significantly fewer GI side effects (4% of cats) compared to oral methimazole (Sartor et al., 2004). When our group compared these methods, there were no differences between routes in the incidence of facial excoriation, neutropenia, thrombocytopenia, or hepatotoxicity. However, transdermal methimazole was associated with somewhat lower efficacy by 4 weeks

(only 67% euthyroid) compared to oral methimazole (82% euthyroid). This may be due to the result of lower bioavailability of the transdermal formulation. Drawbacks of methimazole in PLO include erythema at the dosing site in some cats, increased formulation costs, and unproven drug stability beyond 2 weeks. However, methimazole in PLO appears to be effective (anecdotally) beyond 2 weeks. I recommend that serum T_4 values be checked toward the end of a 2-month prescription of the transdermal formulation to confirm that thyroid control persists.

ADMINISTRATION OF METHIMAZOLE BEFORE PERTECHNETATE SCANNING OR RADIOIODINE THERAPY

Because methimazole does not inhibit iodide uptake by the thyroid, concurrent methimazole therapy does not impair technetium 99m (^{99m}Tc)–pertechnetate thyroid scanning in hyperthyroid cats and in fact may enhance imaging (Fischetti et al., 2005, Nieckarz and Daniel, 2001). However, methimazole does inhibit iodine organification, which may decrease the contact time of radioiodine within the thyroid. Humans given methimazole up to 4 days before radioiodine show no differences in outcome, but administration of methimazole immediately before or after radioiodine has been associated with poorer responses. In hyperthyroid cats retrospective studies have found no association between the time of methimazole discontinuation before radioiodine and long-term radioiodine efficacy (Chun et al., 2002, Forrest et al., 1996). However, without data from a prospective randomized study, discontinuation of methimazole before radioiodine therapy is still recommended. The 1- to 2-week washout period for methimazole recommended by many radioiodine facilities may be longer than necessary but is based on efficacy data from the largest case series published (Peterson and Becker, 1995).

MANAGEMENT OF HYPERTENSION

The prevalence of hypertension in hyperthyroid cats is reported to be 5% to 22%, and many cats with hypertension have concurrent azotemia. Normalizing serum T_4 may not significantly control blood pressure in the first weeks of therapy. Therefore direct management of moderate-to-severe hypertension is indicated along with antithyroid treatment. Commonly used antihypertensive agents include amlodipine, β -blockers, and the angiotensin-converting enzyme (ACE) inhibitors. There is one small clinical trial that has demonstrated a relatively poor response to atenolol in cats in terms of achieving blood pressure control. In cases of moderate to severe hypertension, or when hypertension is associated with target organ injury, amlodipine (starting dose of 0.625 mg PO per cat once or twice daily) is most likely to lower blood pressure effectively. β -blockers such as atenolol are useful if signs of hyperactivity or tachyarrhythmias are present (see Table 39-2). ACE inhibitors such as enalapril or benazepril (0.5 mg/kg once daily) have the potential benefit of reducing intraglomerular pressure in patients with renal disease. However, ACE inhibitors are inferior to amlodipine in control of moderate to severe hypertension.

In those cats in which renoprotective effects of an ACE inhibitor are desired, combination therapy with an ACE inhibitor should be considered (see Chapter 197). In cats with overt azotemia, benazepril, which does not accumulate in renal insufficiency, is preferred by the author over enalapril. In some hyperthyroid cats without initial hypertension, hypertension can actually develop several months after treatment for hyperthyroidism, possibly as a result of unmasking of underlying renal insufficiency. Therefore rechecking cats for hypertension 2 to 3 months after restoration of a euthyroid state is indicated.

OTHER ANTITHYROID DRUG OPTIONS

Propylthiouracil

PTU was the first drug used in the management of hyperthyroid cats in the early 1980s. This drug required high dosages (e.g., 50 mg two to three times daily) to normalize serum T_4 concentrations. PTU was associated with an unacceptably high incidence of adverse events, including positive ANA, Coombs'-positive hemolytic anemia, and thrombocytopenia with bleeding diathesis. Methimazole and PTU share structural similarities; and patients with blood dyscrasias, hepatopathy, or facial excoriation during methimazole treatment may well have similar adverse reactions to PTU. However, the degree of cross-reactivity has not been critically examined in cats.

Carbimazole

Carbimazole is a substituted derivative of methimazole that is a prodrug of methimazole. Carbimazole is used in the United Kingdom for treating cats with hyperthyroidism, and there are anecdotal reports that side effects are less common with carbimazole than with methimazole. This may be related to the fact that plasma methimazole concentrations are approximately 50% lower with carbimazole compared to an identical dose of methimazole. There are no definitive studies comparing the side effect rates of methimazole to carbimazole; and, because carbimazole is converted into methimazole, its use in cats with adverse reactions to methimazole is probably ill advised.

β -Blockers

β -Blockers can reduce the "sympathetic overdrive" characteristic of hyperthyroidism, including tachycardia, arrhythmias, hyperactivity, and aggression. Propranolol has the additional potential benefit of inhibiting the conversion of T_4 to T_3 (see Table 39-2) and may be useful for the short-term management of cats intolerant of methimazole before radioiodine or thyroidectomy. However, as a nonselective β -blocker propranolol can lead to bronchospasm in susceptible cats, and may require three-times daily dosing. Atenolol, a selective β_1 -blocker, is not associated with bronchospasm and is preferred for β_1 -blockade in cats with a prior history of reactive airway disease. Because neither of these treatments normalizes serum T_4 or prevents weight loss, these drugs alone are not appropriate for long-term management of hyperthyroidism. It should be noted that some cats develop a relatively slow

sinus rhythm or even sinus bradycardia after a euthyroid state is achieved, and the dosage of the beta blocker may need to be reduced or the drug discontinued. Some old cats also have atrioventricular conduction disease as a comorbid condition (likely from conduction system degeneration), and beta blockers can result in AV block in susceptible cats. Since atenolol is water soluble and therefore eliminated by renal mechanisms, both heart rate and daily dosage should be reevaluated in cats that develop renal failure following a reduction of serum T_4 .

Iodinated Contrast Agents

Iodinated contrast agents such as ipodate and iopanoic acid inhibit conversion of T_4 to T_3 and have been advocated for use in hyperthyroid cats that do not tolerate methimazole (Murray and Peterson, 1997). Ipodate (Oragrafin; 308mg of iodine per 500mg of calcium ipodate) is no longer marketed, but iopanoic acid (Telepaque; 333mg of iodine per 500mg of iopanoic acid) and diatrizoate meglumine (Gastrografin; 370mg of iodine per milliliter) have been used anecdotally in hyperthyroid cats at comparable doses. Cats may respond initially with decreases in serum T_3 and clinical improvement. However, long-term control is likely to be poor since the effects of these agents are often transient. All iodine-containing agents interfere with thyroid scanning and radioiodine therapy. In humans iopanoic acid must be discontinued 2 weeks before radioiodine therapy, with most patients having a normalized thyroid scan and response to radioiodine by then. Similar data are not available for cats.

Radioiodine for Feline Hyperthyroidism

MARK E. PETERSON, *Bedford Hills, New York*

Hyperthyroidism is the most common endocrine disorder in cats, most frequently associated with adenomatous hyperplasia (or adenoma) involving one or both thyroid lobes. Because the pathogenesis of hyperthyroidism in cats is not known, treatment of the condition is directed at controlling the excessive secretion of thyroid hormone from the adenomatous thyroid gland. Treatment options include administration of antithyroid drugs (see Chapter 39), surgical removal of adenomatous thyroid tissue, and administration of radioiodine. Although each of these treatment options has its advantages and disadvantages, the use of radioiodine is considered by most authorities to be the treatment of choice for most hyperthyroid cats.

Radioactive iodine provides a simple, effective, and safe treatment for cats with hyperthyroidism. It is a particularly useful treatment for cats with bilateral thyroid involvement (found in approximately 70% of cats), cats with ectopic (intrathoracic) thyroid tissue, and the rare feline patient with thyroid carcinoma. Treatment with radioiodine avoids the inconvenience of daily oral administration and side effects associated with antithyroid drugs, as well as the risks and postoperative complications associated with anesthesia and surgical thyroidectomy. Although the therapy is simple and relatively stress free for cats, it does require special licensing and hospitalization facilities, nuclear medicine equipment, and extensive compliance with local and state radiation safety laws. The purpose of this chapter is to give an overview of aspects of radioiodine treatment germane to the practicing veterinarian who is referring hyperthyroid cats for this treatment.

ADVANTAGES OF RADIOIODINE FOR TREATMENT OF HYPERTHYROIDISM

Medical treatment with methimazole is effective in controlling hyperthyroidism in most cats, but for several reasons it may not be the best choice. First, some cats are difficult or impossible to medicate (antithyroid drugs must be administered orally or transdermally, generally one to three times daily). Second, mild reactions (e.g., loss of appetite, vomiting) are common, and a few cats develop serious untoward reactions to the antithyroid drugs (e.g., thrombocytopenia, leukopenia, hepatopathy). Because of the potential for these side effects, periodic blood tests (including complete blood and platelet counts) are necessary to monitor the cat's condition (see Chapter 39). Finally, some owners may not want to have to medicate

their cat on a daily basis for the rest of the cat's life, especially if the cat is only middle-aged.

Surgery is an effective treatment for hyperthyroidism in most cats but may have disadvantages. Many cats with hyperthyroidism have secondary cardiomyopathy and are higher surgical and anesthetic risks; therefore preoperative preparation of hyperthyroid cats with antithyroid drugs or β -adrenergic blocking agent (or concurrent administration of both drugs) is generally recommended. There is also a risk that there will be damage to the adjacent parathyroid glands during thyroid surgery, resulting in transient or, less commonly, permanent hypoparathyroidism and hypocalcemia. This complication can be life threatening and results in extra hospitalization and cost. After surgery cats may occasionally develop hypothyroidism (usually transient), necessitating treatment with thyroid hormone replacement. Finally, there is always the potential that the hyperthyroidism will not be cured with surgical treatment or that the condition will recur a few months to years after successful thyroidectomy. The prevalence that hyperthyroidism will persist or recur is higher among cats that have only one thyroid lobe removed at time of surgery because most cats have adenomatous hyperplasia involving both thyroid lobes. In addition, there is always a chance that one or both of the cat's adenomatous thyroid lobes has descended ventrally below the thoracic inlet or that the cat has hyperfunctional thyroid tissue at ectopic sites. In either case such intrathoracic or ectopic thyroid tissue may be difficult to resect surgically.

Radioiodine therapy has some distinct advantages over use of medical or surgical treatment. Overall, radioiodine provides a simple, effective, and safe treatment for cats with hyperthyroidism. With radioiodine the need for anesthesia and the risk of hypoparathyroidism (the major disadvantages with surgery) are eliminated. Antithyroid drug treatment is not needed; in fact, many treatment centers recommend that drug treatment must be discontinued for a short time (usually 1 to 2 weeks) *before* radioiodine is administered to the cats because lower doses of radioiodine may be needed. The administered radioactive iodine concentrates in and destroys hyperactive thyroid tissue within the cat's body, whether in the normal cervical area or in ectopic sites.

DISADVANTAGES OF RADIOIODINE TREATMENT

As with other major forms of treatment, there are a few disadvantages to the use of radioiodine in cats with

hyperthyroidism. This treatment is not universally available and requires complete knowledge of radiation safety and the use of expensive and sophisticated equipment. The major drawback is that, after administration of radioiodine, the cat must be kept hospitalized for a specified period (7 to 10 days in most treatment centers) and visitation is not allowed. Because of the relatively long isolation period away from the owner, some cats do become depressed; however, it is much more common for the owners to complain of their emotional distress. Most cats tend to do well during the boarding period.

As with any therapy, radioiodine treatment is not perfect. A few cats (< 5%) may not respond adequately to a single treatment, thus requiring retreatment at a later time. Although the reason for such initial treatment failures is not always clear, most of these cats respond well to the second treatment with resolution of their hyperthyroidism.

MECHANISM OF ACTION OF RADIOIODINE TREATMENT

Thyroid hormones are the only iodinated organic compounds in the body. Therefore the only function of ingested iodine is for thyroid hormone synthesis. Ingested stable iodine (^{127}I) is converted to iodide in the gastrointestinal tract and absorbed into the circulation. In the thyroid gland iodide is concentrated or trapped by active transport mechanisms of the thyroid follicular cell, resulting in intracellular iodide concentrations that are 10 to 200 times that of serum. Once inside the thyroid cell, iodide is oxidized to iodine, which is incorporated into tyrosine residues of thyroglobulin (organification) to form the thyroid hormones thyroxine (T_4) and 3,5,3'-triiodothyronine.

The radioisotope used to treat hyperthyroidism is radioiodine-131 (^{131}I). The basic principle behind treatment of hyperthyroidism with ^{131}I is that thyroid cells do not differentiate between stable and radioactive iodine; therefore radioiodine, like stable iodine, is concentrated by the thyroid gland after administration. In cats with hyperthyroidism, radioiodine is concentrated primarily in the hyperplastic or neoplastic thyroid cells, where it irradiates and destroys the hyperfunctioning tissue. Normal thyroid tissue tends to be protected from the effects of radioiodine since the uninvolved thyroid tissue is suppressed and receives only a small dose of radiation (unless very large doses are administered).

When administered to a cat with hyperthyroidism, a large percentage of radioiodine accumulates in the thyroid gland (i.e., most cats extract between 20% to 60% of the administered radioiodine dose from the circulation). The remainder of the administered ^{131}I is excreted primarily in the urine and to a lesser degree the feces. ^{131}I has a half-life of 8 days and emits both β -particles and γ -radiation. The β -particles, which cause 80% of the tissue damage, travel a maximum of 2 mm in tissue and have an average path length of 400 μm . Therefore β -particles are locally destructive but spare adjacent hypoplastic thyroid tissue, parathyroid glands, and other cervical structures.

PATIENT SELECTION AND PREPARATION BEFORE RADIOIODINE TREATMENT

Routine diagnostic testing generally should be performed by the referring veterinarian before referral for radioiodine treatment to determine if the cat is an appropriate candidate for this treatment. This is very important, inasmuch as these cats tend to be middle- to old-aged and therefore may have other geriatric problems unrelated to the cat's hyperthyroidism. Cats should be relatively stable before being considered for radioiodine therapy. Cats that have clinically significant cardiovascular, renal, gastrointestinal, endocrine (e.g., diabetes), or neurologic disease may not be very good candidates for this treatment, especially because of the length of boarding required after the ^{131}I treatment is administered.

The recommended pretreatment workup generally should include the following tests:

- Routine database, including a complete blood count, serum chemistry panel, and urinalysis
- Pretreatment or untreated serum total T_4 concentration (not on antithyroid drug treatment); if the cat has been treated antithyroid for longer than 1 to 2 months, the antithyroid medication might have been discontinued for 5 to 7 days, and another serum total T_4 determined to determine the true severity of the cat's hyperthyroidism
- Chest radiography or cardiac ultrasonography or both should be performed if cat has evidence of any clinically significant cardiac disease (especially pronounced heart murmur, arrhythmia, dyspnea, or jugular venous distension)

Determination of a pretreatment free T_4 concentration alone (without a total T_4 concentration) is generally not acceptable for referral for radioiodine treatment. It is clear that determination of free T_4 concentrations can be very useful in diagnosis of hyperthyroidism, especially in cats in which the disease is suspected but the total T_4 concentration remains within normal range. However, because a high free T_4 concentration also develops in some sick cats that do not have hyperthyroidism and certainly would not benefit from radioiodine treatment, the diagnosis of hyperthyroidism should never be based solely on the finding of a high free T_4 concentration alone. When a free T_4 determination is performed as a diagnostic test for hyperthyroidism, it must always be performed together with a total T_4 concentration.

If concurrent renal disease is suspected or known to be present, many recommend evaluating medical management before a more definitive means of treatment such as radioiodine. In these cats a low starting dose (i.e., 1.25 mg orally once daily) of methimazole with gradual dosage escalation is prudent, with monitoring (e.g., biochemical profile and total serum T_4 determination) and dose adjustments done every 2 weeks. Based on studies regarding changes in glomerular filtration rate (GFR) associated with treatment of hyperthyroidism, it appears that maintenance of euthyroidism for 1 month without azotemia should be sufficient to decide whether to proceed with definitive therapy. Once a cat has stabilized, radioactive iodine could be considered.

The veterinarian may choose to stabilize some cats for a few weeks or months before time of referral for radioiodine treatment by administering cardiovascular medications, β -blocking agents, or antithyroid drugs (see Chapter 39). Although concurrent administration of β -blocking agents does not interfere with radioiodine treatment, one should realize that prior or concurrent antithyroid drug treatment may influence the effectiveness of the radioiodine treatment, resulting in treatment failure. The effect of prior methimazole treatment on eventual outcome of radioactive iodine therapy in cats is controversial, however; and it has been variably suggested to worsen, enhance, or have no effect on radioiodine treatment. The thyroidal uptake of radioiodine is enhanced in healthy cats after recent methimazole withdrawal, and this short-term rebound effect may be potentially beneficial when treating hyperthyroidism in cats with radioactive iodine. Some have theorized that this enhanced thyroidal uptake of radioiodine therapy may lead to a higher incidence of radioiodine-induced hypothyroidism. However, other studies have shown that discontinuing methimazole for less than or greater than 5 days before radioactive iodine therapy has no effect on treatment outcome.

Overall, if antithyroid drugs have been administered, most treatment centers recommend that they be discontinued for at least 1 week before treatment with radioiodine. In some cats with severe, life-threatening hyperthyroidism or concurrent disease (e.g., renal failure), one may decide that is not wise to stop antithyroid drug treatment but to treat with antithyroidal drugs while the cat is still receiving the radioiodine administration. Such cases must be discussed with the radioiodine treatment center before the referral.

ESTIMATION OF THE RADIOIODINE DOSE TO ADMINISTER

Ideally administration of radioiodine restores euthyroidism with a *single* dose without inducing hypothyroidism. Numerous methods to calculate the administered radioiodine dose to cats with hyperthyroidism have been described, but the optimal method for determining the amount of radioactivity required for effective treatment in cats remains somewhat controversial. The reported methods used to calculate the radioiodine dose are quite variable but can be divided into three different methodologies.

The first method of determining the proper dose is to use tracer kinetic studies to estimate the percentage of iodine uptake and rate of disappearance from the gland and thyroid imaging to estimate the weight of the gland; the dose of radioiodine is then calculated from these measurements. Although this method of dose determination theoretically should produce the best results, measurement of the biologic half-life of iodine in hyperthyroid cats using tracer techniques has been shown to be a poor predictor of the biologic half-life of iodine following radioiodine therapy. Presumably this discrepancy originates with the changes in thyroid physiology that develop following the delivery of large doses of radiation to the thyroid gland. As a result, there can be a marked difference between the calculated dose of radioiodine and the actual

dose delivered to the cat's thyroid tissue. Because of this poor correlation, most centers that treat hyperthyroid cats with radioiodine no longer calculate the cats' radioiodine doses based on measurements of the biologic half-life and uptake of iodine.

A second method of treating hyperthyroid cats is to administer a fixed, relatively high dose of radioiodine to all cats (i.e., 4 mCi or 5 mCi), regardless of the severity of hyperthyroidism or size of the thyroid tumor. To accomplish a reasonable success rate, the fixed dose method uses a radioiodine dose (4 to 5 mCi) that is above the median dose reported (3 mCi) for individualized dosing methods. As a result, a large number of cats treated using this method receive excessive amounts of radioiodine exposing both the patient and veterinary personnel to unnecessary levels of radiation. Although this method is the simplest, use of this approach results in undertreatment of a few cats with severe disease but more commonly overtreatment of a number of cats with mild disease.

In the third method of dose determination the dose of radioiodine administered to hyperthyroid cats is determined on the basis of a scoring system that takes into consideration the severity of clinical signs, the size of the cat's thyroid gland (based on either physical palpation or results of thyroid imaging, and the serum T_4 concentration). Using this scoring system, a low, medium, or relatively high ^{131}I dose is selected without determining thyroid gland kinetics. For example, cats with mild clinical signs, small thyroid tumors, and only slightly high serum T_4 concentrations would receive smaller doses of radioiodine (e.g., 3 mCi); cats with severe clinical signs, very large thyroid tumors, and markedly high serum T_4 concentrations would receive high doses of radioiodine (i.e., 5-6 mCi); and cats that lie between these extremes would receive intermediate doses of radioiodine (e.g., 4 mCi). This approach has been shown to provide treatment results comparable to those obtained when thyroid kinetics were determined (i.e., the first method of dose determination). The major advantage of this method is that nuclear medicine equipment is not needed, the time required to determine thyroid kinetics is eliminated, and sedation of the cat is not required. In addition, in contrast to the fixed dose method, the total radiation dosage delivered to the cats with mild hyperthyroidism was minimized since lower doses are given to these cats.

Radioiodine can be administered to cats intravenously or orally, but the subcutaneous route is preferred. The subcutaneous route has been shown to be equally as effective as the other routes of administration, not associated with gastrointestinal side effects, and safer for personnel. In addition, the dose can usually be administered with no or only light sedation, thereby avoiding anesthesia.

In cats with thyroid carcinoma (incidence <2.5% of all hyperthyroid cats), radioiodine offers the best chance for successful cure of the tumor because it concentrates in all hyperactive thyroid cells (i.e., carcinomatous tissue, as well as metastasis). However, thyroid carcinomas concentrate and retain iodine less efficiently than thyroid adenomas (adenomatous hyperplasia), and the size of carcinomas is usually much larger; therefore extremely high doses of radioiodine (10 to 30 mCi) are almost always needed for destruction of all malignant tissue. The combination of

surgical debulking followed by administration of high-dose radioactive iodine also has been reported to be successful in cats with thyroid carcinoma. Longer periods of hospitalization are required with use of such high-dose radioiodine administration because of the prolonged radioiodine excretion.

RADIATION SAFETY PRECAUTIONS DURING THE HOSPITALIZATION PERIOD

Regardless of the method of dose determination selected, certain radiation safety restrictions and procedures must be followed after the radioiodine dose has been administered. The cats must be confined to a restricted and shielded area of the hospital (e.g., nuclear medicine isolation ward) that has minimal traffic. Also, the cats should be housed in appropriate cages so that urine and feces can be collected safely.

Personnel are restricted in the ward housing the cats, and only those properly trained in radiation safety and closely monitored are allowed into the ward. All personnel handling the cats, cages, food dishes, and excreta are required to wear protective clothing (e.g., long laboratory coats), disposable plastic gloves, and dosimeter monitors (film badges). All material removed from the cage must be handled as radioactive waste and stored until disposed of accordingly.

If the cat becomes ill during the quarantine period (a very rare occurrence when cats are selected carefully), it should be remembered that contact of veterinary personnel with the cat also should be limited, and special arrangements may be required for hospitalization. Clinical laboratories may decline to accept samples from patients during the quarantine period.

The cats are discharged from the hospital when the radiation dose rate has decreased to a safe level that has been determined by the radiation control office. Cats are hospitalized to protect people from radiation exposure, not because the cats require medical care. The hospitalization period varies from cat to cat and usually is approximately 7 to 10 days in most treatment centers for cats treated with typical radioiodine dosages. Cats treated with higher dosages (e.g., for functional thyroid carcinoma) may require longer hospitalization periods.

RADIATION SAFETY PRECAUTIONS AFTER DISCHARGE FROM THE HOSPITAL

On discharge the cats still excrete a small amount of radioiodine in their urine and feces. The remaining radioactivity is eliminated gradually from the cat over the next 2 to 4 weeks through radioactive decay and excretion into the urine and feces. However, until this is complete, the cat continues to emit low levels of radiation.

Owners must obey some safety precautions after their cat is discharged following ^{131}I treatment. These precautions are dictated by federal, state, and local laws and are designed to protect humans from excessive radiation exposure. These laws usually require keeping the cat strictly indoors for a period of time after treatment (e.g., 2 weeks), spell out the amount of contact time each person should have with the cat daily during this period

(10 to 20 minutes per person), and dictate how the owner should dispose of or store the cat's waste. Contact with children and pregnant woman during the first 2 weeks is usually prohibited.

In general, if the owner cannot avoid close, prolonged contact with the cat, it is generally recommended that the cat be boarded during this period. Additional information concerning handling of the cat on release to the owners and related radiation safety issues should be discussed with the veterinarian in charge of the radioiodine therapy.

ADVERSE EFFECTS/COMPLICATIONS ASSOCIATED WITH RADIOIODINE TREATMENT

Overall, side effects associated with radioiodine treatment of cats are extremely rare. Because radioiodine is relatively specific in its site of action, there is no hair loss or increase in skin pigmentation, as may be seen with external radiation therapy (cobalt radiation). In rare instances cats develop transient dysphagia (i.e., difficult swallowing) and fever during the first few days after treatment (probably as a result of radiation thyroiditis), but this condition is self-limited and resolves spontaneously. Rarely, they can develop a voice change after treatment, which may be permanent in some cases. A more serious problem directly caused by radioiodine treatment in cats is permanent hypothyroidism (see following paragraphs), which develops a few months after treatment with radioiodine in a small percentage of cats.

Most consider the development or worsening of renal disease to be the most serious complication of radioiodine treatment. However, if renal disease does develop, it is not caused by the radioiodine itself but rather because, by correcting the hyperthyroid state, the GFR and renal blood flow fall as the cat's cardiovascular status returns to normal. One must remember that hyperthyroidism itself may contribute to the development of renal disease in cats. Systemic hypertension, relatively common in cats with hyperthyroidism, can lead to an increase in glomerular capillary pressure and proteinuria, which may contribute to glomerular sclerosis and progression of renal disease.

In some cats untreated hyperthyroidism can mask pre-existing, "hidden" renal disease by increasing the blood flow to the kidneys, which may become clinically apparent *only* after return of normal thyroid function. High renal blood flow associated with the hyperdynamic circulation that accompanies untreated hyperthyroidism may be beneficial in maintaining sustainable renal function, as well as in delaying the clinical and biochemical consequences of severe renal failure in some cats with chronic renal failure.

This development of azotemia occurs independently of treatment modality (i.e., it occurs with methimazole, surgical thyroidectomy, or radioiodine). Although the exact incidence of such deterioration in renal function is still under investigation, it is my estimate that some worsening in serum urea nitrogen or creatinine concentrations occurs in about 25% of treated cats. Such azotemia typically develops within 30 days after treatment of hyperthyroidism, but the azotemia tends to remain stable in most cats.

Other than the possible association between treatment of hyperthyroidism and the acute development of overt T_4 renal disease in a few cats, the long-term risk associated with administration of radioiodine to cats appears to be minimal. Therapeutic doses of radioiodine irradiate not only the thyroid gland but the whole body to some degree; this raises concerns about possible long-term effects such as carcinogenesis, genetic damage, and fetal damage. However, a number of recent studies of large populations of humans treated with radioiodine have failed to demonstrate increased risk of death from thyroid cancer, leukemia, or cancer in general. Likewise, increased risk of genetic abnormality in offspring of humans administered radioiodine has not been identified. Obviously this is less of a concern in cats with hyperthyroidism because most are usually neutered before hyperthyroidism develops.

FOLLOW-UP THYROID FUNCTION TESTING AFTER RADIOACTIVE IODINE TREATMENT

The ideal goal of ^{131}I therapy is to restore euthyroidism with a single dose of radiation without producing hypothyroidism. Indeed, most hyperthyroid cats treated with radioactive iodine are cured by a single dose. Thyroid hormone concentrations in the blood are normal within 2 weeks of therapy in approximately 85% of cats and in 95% of cats by 3 months. Although cats appear to feel better within days after treatment, the owner will notice gradual clinical improvement and resolution of the signs of hyperthyroidism over a 1- or 3-month period.

Approximately 5% of cats fail to respond completely and remain hyperthyroid after treatment with radioiodine. In studies from our institution, most cats with persistent hyperthyroidism had large thyroid tumors, severe hyperthyroidism, and very high serum T_4 concentrations. One explanation for persistent hyperthyroidism in these cats with large tumors and severe hyperthyroidism is that a greater number of adenomatous cells must be destroyed compared to cats with small tumors and mild disease. If these cats are not retreated, their signs of hyperthyroidism usually return a few months later. Therefore, if the hyperthyroid state persists for longer than 3 months after initial treatment, the referring veterinarian should discuss the possibility of again treating the cat with radioiodine with the veterinarian in charge of the radioiodine facility. In such cats retreatment is generally recommended because virtually all cats that remain hyperthyroid after the first treatment can be cured by a second treatment.

After treatment with radioiodine, it is common to see a transient fall in serum T_4 concentrations for a few weeks; but associate clinical signs of hypothyroidism do not develop, and treatment is almost never required. In most of those cats, free T_4 and thyroid-stimulating hormone (TSH) concentrations remain within reference range limits. In contrast, a few (less than 5%) of cats treated with radioiodine develop permanent hypothyroidism, with clinical signs developing 2 to 4 months after treatment. Clinical signs associated with iatrogenic hypothyroidism in these cats may include lethargy, nonpruritic seborrhea sicca, matting of hair, and marked weight gain; bilateral

symmetric alopecia does not develop. Diagnosis is based on the cat's clinical signs, findings of low serum total and free T_4 concentrations (especially in combination with a high serum TSH concentration), and the response to replacement therapy. If hypothyroidism does develop, lifelong thyroid hormone supplementation is generally needed (i.e., 0.1 mg of L- T_4 per day).

After administration of radioiodine to cats, cure of hyperthyroidism is generally permanent, but recent studies have demonstrated that the disorder can recur. However, relapse is very uncommon, with a prevalence of less than 5%; and the time between treatment with radioiodine and relapse is generally 3 or more years. Therefore such relapse might indicate the development of new hyperplastic or neoplastic nodules arising from any remaining normal thyroid tissue rather than recurrence of the first adenomatous thyroid tumor that was treated with radioiodine. Nevertheless, the fact that both hypothyroidism and relapse can occur after treatment of cats with radioiodine indicates that continued, periodic monitoring of thyroid function (e.g., at least once yearly) is advisable once euthyroidism is restored.

The ongoing treatment of comorbid conditions such as systemic hypertension (see Chapters 30 and 197), cardiomyopathy (see Chapter 178), and renal failure requires clinical judgment and is approached on a case-by-case basis. Since geriatric cats are affected by a number of renal, cardiovascular, and gastrointestinal diseases, the clinician must appreciate that resolution of hyperthyroidism may not always resolve unrelated medical disorders. However, the vast majority of treated cats are improved clinically and appear to achieve a better quality of life.

Hypothyroidism

J. CATHARINE R. SCOTT-MONCRIEFF, *West Lafayette, Indiana*

Clinical signs of hypothyroidism result from decreased production of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) by the thyroid gland. Acquired primary hypothyroidism is the most common form of the disease and usually is caused by either lymphocytic thyroiditis or idiopathic thyroid atrophy. Secondary hypothyroidism (deficiency of thyroid-stimulating hormone [TSH]) is less commonly recognized in the dog.

ETIOLOGY

Approximately 50% of cases of primary hypothyroidism are caused by lymphocytic thyroiditis. Grossly the thyroid gland may be normal or atrophic; whereas histologically there is multifocal or diffuse infiltration of the thyroid gland by lymphocytes, plasma cells, and macrophages. As thyroiditis progresses, the parenchyma is destroyed and replaced by fibrous connective tissue. Initially thyroiditis may be subclinical but usually progresses over time to cause overt hypothyroidism. Idiopathic thyroid atrophy, in which there is loss of thyroid parenchyma and replacement by adipose and connective tissue, may be caused by end-stage thyroiditis. Canine thyroiditis is believed to be immune mediated, and antithyroglobulin antibodies (ATAs) are a sensitive marker of thyroid inflammation. Approximately 50% of hypothyroid dogs have ATAs; however, the prevalence varies widely among breeds, which reflects a familial tendency for thyroiditis and resultant hypothyroidism.

SIGNALMENT

Any breed may develop hypothyroidism; however, some breeds such as the golden retriever and the Doberman pinscher have been reported to be at higher risk. Thyroiditis is clearly heritable in the beagle; the borzoi; and many other common breeds such as the golden retriever, Great Dane, Irish setter, Doberman pinscher, and Old English sheepdog have a high prevalence of ATAs (Nachreiner et al., 2002). The rate of clinical progression of thyroiditis also varies among breeds. In beagles the prevalence of thyroiditis is as high as 40%, but if the progression to hypothyroidism occurs at all, it occurs in middle age or later (Scott-Moncrieff et al., 2006). In other breeds such as the golden retriever, thyroiditis appears to progress more rapidly, with peak onset of hypothyroidism at 5 years of age but with some dogs diagnosed as young as 2 years of age. Overall middle-aged dogs are at increased risk of hypothyroidism. In one study mean age at diagnosis was

7 years with a range of 0.5 to 15 years. Spayed females and neutered male dogs are at increased risk for developing hypothyroidism compared with sexually intact animals.

CLINICAL SIGNS

Clinical signs of hypothyroidism are usually nonspecific and insidious in onset, and hypothyroidism is commonly misdiagnosed. Clinical signs that occur as a result of decreased metabolic rate include lethargy, mental dullness, weight gain, unwillingness to exercise, and cold intolerance. Dermatologic findings include dry scaly skin, changes in hair coat quality or color, symmetric alopecia, seborrhea, and superficial pyoderma. Hyperkeratosis, hyperpigmentation, comedone formation, hypertrichosis, ceruminous otitis, poor wound healing, increased bruising, and myxedema may also occur. Alopecia is usually bilaterally symmetric and is first evident in areas of wear, whereas the head and extremities tend to be spared. The hair may be brittle and easily epilated, and loss of undercoat or primary guard hairs may result in a coarse appearance or a puppylike hair coat. Fading of coat color may also occur, and failure of hair regrowth after clipping is common. Hypothyroid dogs are also predisposed to recurrent bacterial infections of the skin. Myxedema (cutaneous mucinosis) is a rare dermatologic manifestation of hypothyroidism, caused by deposition of hyaluronic acid in the dermis and characterized by non-pitting thickening of the skin, especially of the eyelids, cheeks, and forehead. A rare complication of myxedema is cutaneous mucinous vesiculation.

Reproductive dysfunction has been attributed to hypothyroidism. In male dogs low libido, testicular atrophy, hypospermia, and azoospermia have been reported; whereas hypothyroid bitches may develop prolonged interestrous interval, silent estrus, failure to cycle, spontaneous abortion, small or low-birth weight litters, uterine inertia, and weak or stillborn puppies. However, in both sexes evidence for an association between reproductive signs and hypothyroidism is weak. Inappropriate galactorrhea, apparently caused by hyperprolactinemia, has been reported in sexually intact hypothyroid bitches.

Both the peripheral and central nervous systems may be affected by hypothyroidism. Peripheral neuropathy is the best documented neurologic manifestation. Affected dogs have exercise intolerance, weakness, ataxia, quadriplegia or paralysis, deficits of conscious proprioception, and decreased spinal reflexes. Clinical signs resolve with levothyroxine (L -thyroxine) supplementation. A subclinical myopathy also occurs in hypothyroid dogs. Unilateral

lameness reported in hypothyroid dogs may be a manifestation of generalized neuromyopathy.

Dysfunction of multiple cranial nerves (facial, trigeminal, vestibulocochlear) and abnormal gait and postural reactions are also reported in hypothyroidism. Hypothyroid dogs with vestibular deficits have abnormal brainstem auditory-evoked responses, and some dogs also have electromyographic abnormalities in appendicular muscles. Clinical signs resolve with L-thyroxine supplementation. Although laryngeal paralysis and megaesophagus have been reported in association with hypothyroidism, treatment of hypothyroidism does not consistently result in resolution of clinical signs, and a causal relationship has not been confirmed. Myasthenia gravis has been reported in association with hypothyroidism. Concurrent hypothyroidism may exacerbate clinical signs of myasthenia gravis such as muscle weakness and megaesophagus.

In rare instances cerebral dysfunction occurs in hypothyroidism as a result of myxedema coma, atherosclerosis, or the presence of a pituitary tumor causing secondary hypothyroidism. Seizures, disorientation, and circling may occur as a result of severe hyperlipidemia or cerebral atherosclerosis; however, there is little evidence to suggest that hypothyroidism is a common cause of seizure disorders in dogs. In myxedema coma profound mental dullness or stupor may be accompanied by nonpitting edema, hypothermia with a lack of shivering, bradycardia, weakness, and inappetence. Concurrent disease, especially infection, is a common precipitating factor.

Behavioral abnormalities that have been attributed to canine hypothyroidism include aggression and cognitive dysfunction. Myxedema coma and atherosclerosis clearly can cause cognitive dysfunction in some individuals; however, these manifestations of hypothyroidism are rare. Evidence for a causal association between common behavioral problems and hypothyroidism is lacking.

Abnormalities of the cardiovascular system such as sinus bradycardia, weak apex beat, low QRS voltage, and inverted T waves occur in hypothyroid dogs. Reduced left ventricular pump function has also been documented, and hypothyroidism may exacerbate clinical signs in dogs with underlying cardiac disease. Although hypothyroidism rarely causes clinically significant myocardial failure in dogs, dilated cardiomyopathy and hypothyroidism may occur concurrently. Long-term improvement in cardiac function was reported after treatment with L-thyroxine in two Great Danes with concurrent dilated cardiomyopathy and hypothyroidism.

Ocular abnormalities reported in canine hypothyroidism include corneal lipidosis, corneal ulceration, uveitis, lipid effusion into the aqueous humor, secondary glaucoma, lipemia retinalis, retinal detachment, and keratoconjunctivitis sicca. However, a definite causal relationship has not been proven.

Congenital hypothyroidism results in mental retardation and stunted disproportionate growth caused by epiphyseal dysgenesis and delayed skeletal maturation. Affected dogs are mentally dull and have large broad heads, short thick necks, short limbs, macroglossia, hypothermia, delayed dental eruption, ataxia, and abdominal distention. A palpably enlarged thyroid

gland may also be present, depending on the cause of the congenital defect. Other clinical signs include gait abnormalities, stenotic ear canals, sealed eyelids, and constipation. Affected puppies are often the largest in the litter at birth but start to lag behind their littermates within 3 to 8 weeks of age. Many severely affected puppies likely die without a diagnosis in the first few weeks of life. Congenital hypothyroidism with goiter caused by thyroid peroxidase deficiency has been recognized in toy fox terriers and rat terriers (Fyfe et al., 2003). The defect is an autosomal-recessive trait, and a nonsense mutation in the thyroid peroxidase gene of affected dogs has been identified. A deoxyribonucleic acid test that will detect carriers of the defect is available to screen breeding animals through the laboratory of comparative medical genetics at Michigan State University.

DIAGNOSIS OF HYPOTHYROIDISM

A clinical suspicion of hypothyroidism should be obtained by evaluation of the signalment; history and physical examination; and results of a hemogram, biochemical panel, and urinalysis. Measurement of total T_4 concentration is a sensitive initial screening test for hypothyroidism. Tests to confirm the diagnosis include measurement of free T_4 and TSH concentration, provocative thyroid function tests, and antibody tests for thyroiditis. In some equivocal cases evaluation of response to thyroid hormone supplementation is necessary to confirm the diagnosis.

Clinical Pathology

Clinicopathologic changes that are commonly observed in dogs with hypothyroidism are normocytic, normochromic, nonregenerative anemia, fasting hypertriglyceridemia, and hypercholesterolemia.

Basal Thyroid Hormone Concentrations

T_4 is the major secretory product of the thyroid gland, whereas the majority of serum T_3 is derived from the extrathyroidal deiodination of T_4 . Both T_3 and T_4 are highly protein bound to serum carrier proteins. Only unbound (free) hormone penetrates cell membranes, binds to receptors, and has biologic activity. Protein-bound hormone acts as a reservoir and buffer to maintain a steady concentration of free hormone in the plasma despite rapid alterations in release and metabolism of T_3 and T_4 and changes in plasma protein concentrations. Free T_4 is mono-deiodinated within cells to T_3 , which binds to receptors and induces the cellular effects of thyroid hormone. Diagnostic performance of basal thyroid hormone measurements in the diagnosis of canine hypothyroidism is shown in Table 41-1.

Total Thyroxine Concentration

Total T_4 concentration is the most commonly performed static thyroid hormone measurement and is a good initial screening test for canine hypothyroidism. In general a dog with a T_4 concentration well within the normal range may be assumed to have normal thyroid function; however, a basal T_4 concentration below the normal

Table 41-1

Performance of Various Diagnostic Tests for Hypothyroidism in Dogs

	Sensitivity (%)	Specificity (%)	Accuracy (%)
Total T ₄	89-100	75-82	85
Free T ₄	80-98	93-94	95
TSH	63-87	82-93	80-84
TSH/T ₄ *	63-67	98-100	82-88
TSH/free T ₄ *	74	98	86

The data are compiled from three published studies of a total of 100 hypothyroid dogs and 164 euthyroid dogs. Not all studies evaluated all diagnostic tests listed. T₄, Thyroxine; TSH, thyroid-stimulating hormone.

*A dog was considered to have hypothyroidism only if the T₄ or free T₄ was low and the TSH was high.

range is not diagnostic for hypothyroidism. In this case the dog may be normal, hypothyroid, or suffering from a nonthyroidal illness with a secondary decrease in the basal T₄ concentration (sick euthyroid syndrome). Factors such as time of day, age, breed, and ambient temperature may affect the total T₄ concentration without altering metabolically active free thyroid hormone concentrations. Not only does the T₄ concentration in *normal* dogs commonly fluctuate out of the reference range, but a number of breeds (e.g., Greyhounds, conditioned sled dogs) have been identified as having T₄ concentrations lower than established laboratory reference ranges (Evason et al., 2004; Lee et al., 2004). A significant decline in basal T₄ concentration with age adds yet another variable; estrus, pregnancy, obesity, and malnutrition also influence the basal T₄. There may also be a marked effect of some drugs on the thyroid axis (Table 41-2) (Daminet et al., 2003). Systemic illnesses that may decrease basal T₄ concentrations include hyperadrenocorticism, diabetes mellitus, hypoadrenocorticism, renal failure, hepatic failure, and infection. Interference by anti-T₄ antibodies can cause a spurious increase in the measured T₄ concentration, but this is usually to a value above the reference range.

Free Thyroxine Concentration

Because only the unbound fraction of serum T₄ is biologically active, measurement of free T₄ is more sensitive and specific than total T₄ in differentiation of euthyroid dogs from hypothyroid dogs, providing free T₄ assays that use equilibrium dialysis (ED) rather than analog methods. Free T₄ measured by ED is unaffected by antibody interference. Although the free T₄ concentration is a more accurate stand-alone test than the basal T₄, significant concurrent disease can cause a decrease in free T₄, and the assay is approximately twice as expensive in most commercial laboratories as the total T₄.

Total Triiodothyronine Concentration

In euthyroid dogs T₃ concentration fluctuates in and out of the normal range even more than T₄ concentration; therefore T₃ concentrations are less accurate in distinguishing euthyroid from hypothyroid dogs. Spurious T₃ measurements may also occur because of the presence of anti-T₃ antibodies that interfere with the T₃ assay.

Thyroid-Stimulating Hormone Concentration

Measurement of canine TSH concentration is helpful in dogs with a low total T₄ concentration because a low

Table 41-2

Effect of Drug Treatment on Thyroid Function Testing in Dogs

Drug	TT ₄ (↓ or N)	Free T ₄ (↓ or N)	TSH (↑ or N)	Clinical signs of hypothyroidism? (Y/N)*	Notes
Glucocorticoids	↓	(↓ or N)	N	N	Effect dose and duration dependent
Phenobarbital	↓	↓	Slight ↑	N	Thyroid-stimulating hormone not increased outside reference range
Trimethoprim/sulfonamides	↓	↓	↑	Y	Effect dose and duration dependent
Nonsteroidal antiinflammatory drugs	↓	N	N or ↓	N	Effect varies, depending on specific drug used

N, No change; TSH, thyroid stimulating hormone; TT₄, thyroxine; ↑, increased; ↓, decreased.

*N, No; Y, yes.

T₄ in conjunction with a high TSH is highly specific for diagnosis of hypothyroidism (Table 41-3). The main disadvantage of measuring TSH is the lack of sensitivity of this assay because, for reasons that are unclear, approximately 30% of hypothyroid dogs have a TSH concentration within the reference range.

Thyroid-Stimulating Hormone Stimulation Test

The TSH stimulation test is a test of thyroid reserve. It is considered the gold standard test of thyroid function in dogs, but its use is limited by the expense and availability of TSH. The protocol requires collection of a serum sample for measuring T₄, administration of bovine TSH intravenously (IV) at a dose of 0.1 units/kg (maximum dose 5 units), followed by collection of a second sample for measurement of T₄ 6 hours later. Alternatively human recombinant TSH (Thyrogen, Genzyme Corp.) may be used at a dose of 50 to 100 mcg IV with collection of 0- and 4 to 6-hour samples. One vial contains 1.1 mg of lyophilized TSH; after reconstitution it may be frozen for at least 8 weeks with no loss of potency. Current cost is approximately \$1800 and contains enough TSH for 10 to 20 dogs. Bovine TSH currently is only available as the chemical grade preparation, and there have been reports of adverse effects after administration of this product.

Results of the TSH stimulation test may reveal a normal response, a blunted response (sick euthyroid syndrome), or no response (hypothyroidism). A diagnosis of hypothyroidism can be confirmed if both the basal and the post-T₄ samples are below the reference range for basal total T₄ concentration. A euthyroid state is confirmed if the post-T₄ concentration is greater than 2.5 to 3 mcg/dl. Interpretation of intermediate results is more difficult and should take into consideration the clinical signs and severity of concurrent systemic disease.

Thyroid-Releasing Hormone Stimulation Test

In dogs this test has been used predominantly to evaluate thyroid gland function by measuring a change in T₄ concentration after thyroid-releasing hormone (TRH) admin-

istration. Unfortunately the change is not as large as after TSH administration, and some dogs with normal thyroid function have a decreased response to TRH. For this reason the test is of limited clinical use. Current protocols recommend a fixed dose of 100 to 600 mcg TRH IV, with samples collected at 0 and 4 hours.

Thyroid Ultrasound

Measurement of thyroid gland size by ultrasound is a useful adjunctive test for differentiating between hypothyroid and euthyroid dogs (Brömel et al., 2005; Reese et al., 2005). Identification of both decreased thyroid volume and maximal cross-sectional area have high specificity for diagnosis of hypothyroidism; however, because some hypothyroid dogs have thyroid volumes within the reference range, ultrasonography lacks sensitivity for diagnosis of hypothyroidism. It is important that thyroid ultrasonography is performed by an operator with experience in performing and interpreting ultrasound studies of the cervical region.

Therapeutic Trial

In some cases the most practical approach to confirming a diagnosis of hypothyroidism is a therapeutic trial. Every attempt should be made to rule out nonthyroidal illness before starting a therapeutic trial. Supplementation with L-thyroxine should be initiated at a dose of 20 mcg/kg (0.1 mg/10 lb) every 12 hours. Few studies in dogs document the comparative efficacy of available T₄ supplements; however, the impact of differences in product bioavailability can be minimized if therapeutic monitoring is used to guide the final dose administered (Fig. 41-1). If possible, objective criteria should be used to assess response to treatment. If a positive response to treatment occurs, the clinician should be prepared to withdraw therapy to confirm that clinical signs return. This ensures that dogs with thyroid-responsive diseases (diseases in which the clinical signs improve because of the nonspecific effects of thyroid hormone or unrelated to therapy) do not remain on thyroid supplementation for life. If there is no response to treatment after 2 to 3 months of appropriate therapy

Table 41-3		
Interpretation of Basal Thyroid Hormone Concentrations (T ₄ , Free T ₄ , TSH)		
	Normal T ₄ /Free T ₄	Low/Borderline T ₄ /Free T ₄
Normal TSH	Normal dog Only consider further thyroid testing if strong clinical suspicion of hypothyroidism	Hypothyroid, normal variation, or concurrent illness Consider further diagnostic evaluation of thyroid function (thyroid autoantibodies, provocative testing) or therapeutic trial.
High TSH	Early subclinical hypothyroidism or recovery from concurrent illness Consider reevaluation of thyroid function in 1-3 months; if strong clinical suspicion for hypothyroidism, evaluate for thyroiditis	Hypothyroid Lifelong therapy with L-thyroxine is indicated; use therapeutic monitoring to adjust dose

T₄, Thyroxine; TSH, thyroid-stimulating hormone.

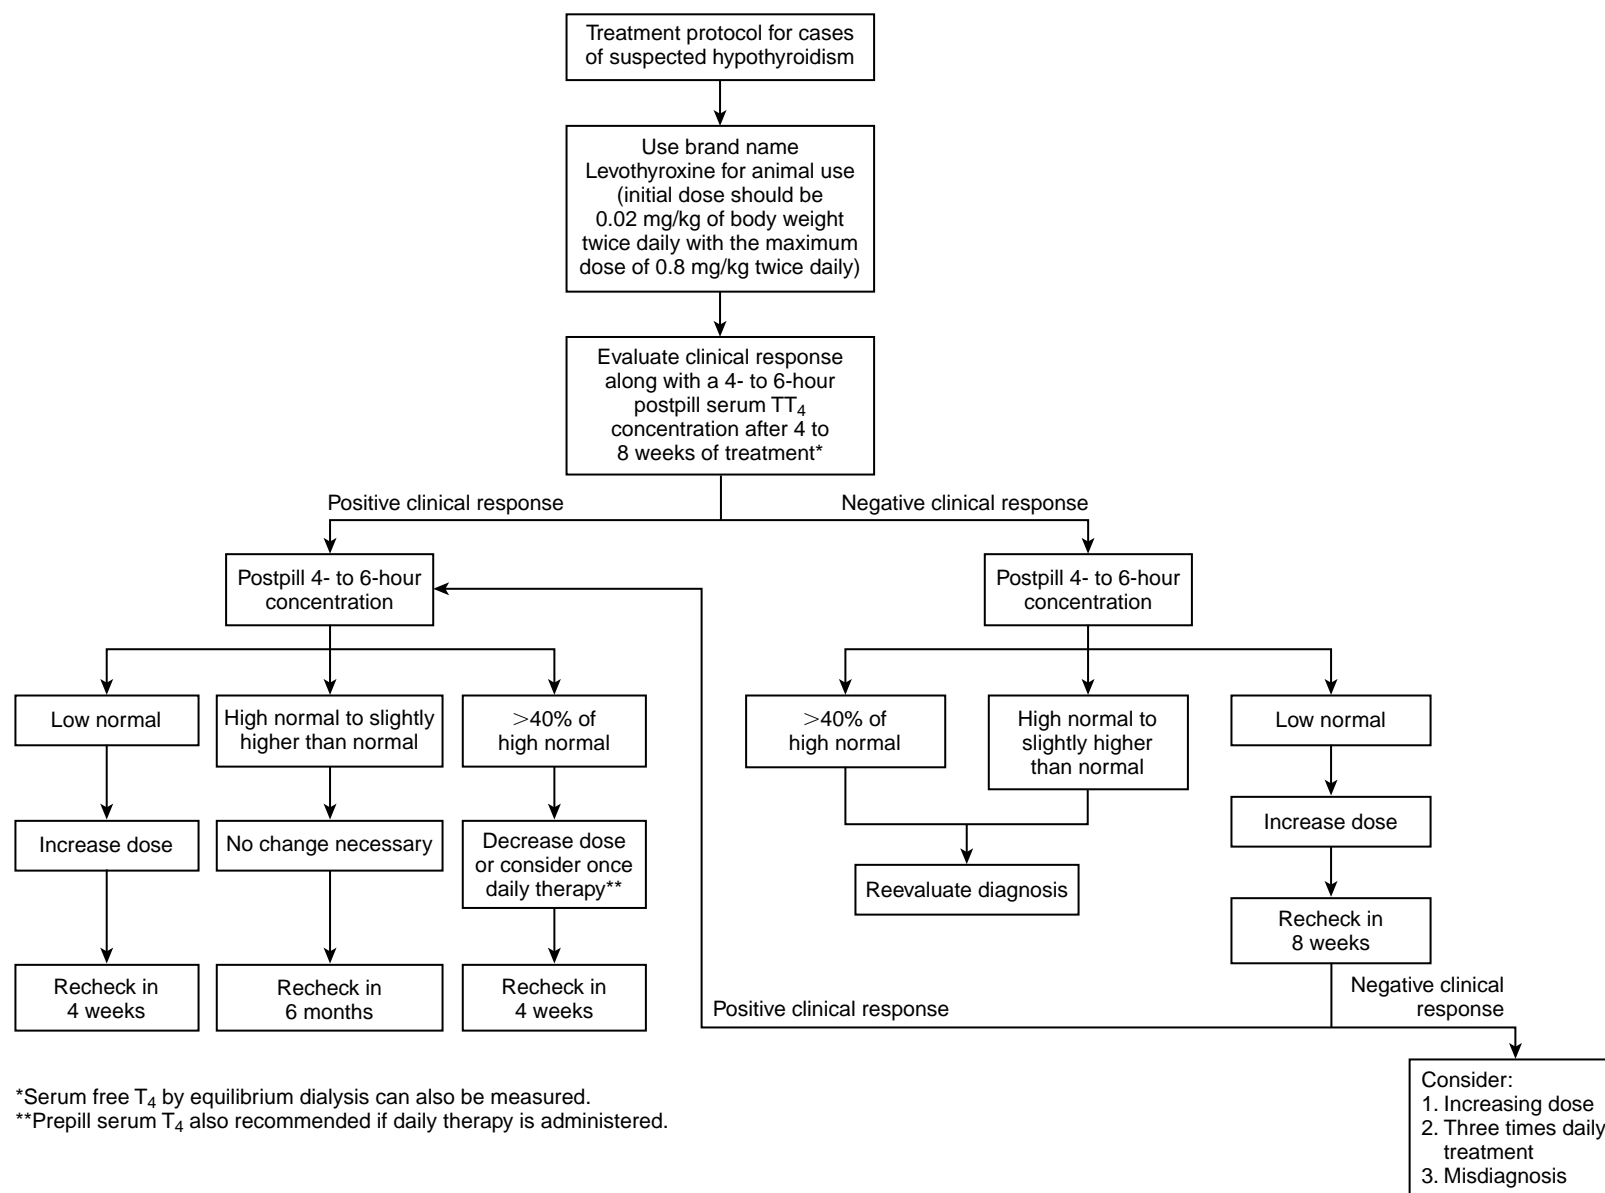

Fig 41-1 Algorithm outlining approach to treatment of canine hypothyroidism. (From Scott-Moncrief JCR, Guptill-Yoran L: Hypothyroidism. In Ettinger SJ, Feldman EC: *Textbook of veterinary internal medicine: diseases of the dog and cat*, ed 6, 2005, Elsevier.)

in the face of adequate serum T_4 concentrations, the clinician should be prepared to withdraw therapy and pursue other diagnoses.

Recommendations for Thyroid Testing

Initial evaluation of thyroid function is best made by measurement of either total T_4 or ideally free T_4 in conjunction with TSH. Further testing should be pursued when initial testing results are equivocal (see Table 41-3 and Chapter 38).

DIAGNOSIS OF THYROIDITIS

Antithyroglobulin Antibodies

ATAs are found in approximately 50% of hypothyroid dogs and are believed to be the result of leakage of thyroglobulin into circulation caused by lymphocytic thyroiditis. A commercially available enzyme-linked immunosorbent assay for ATAs appears to be a fairly sensitive and specific indicator of thyroiditis, although false-positive results do occur. Because ATAs are more common in hypothyroid dogs than euthyroid dogs, their presence may be useful in assessing thyroid function in dogs when other tests of thyroid function are equivocal. However, it is important to recognize that a positive ATA titer can occur in euthyroid dogs. The proportion of euthyroid dogs with ATAs that ultimately develop hypothyroidism is unknown. In one study approximately 20% of euthyroid dogs with thyroiditis developed some evidence of thyroid dysfunction within a year. A small percentage of dogs (15%) became ATA negative after 12 months. Possible causes for a transient increase in ATAs include recent vaccination, drug therapy, or viral infection.

Measurement of ATAs has been advocated for screening breeding stock with the aim of ultimately eliminating heritable forms of thyroiditis. The Orthopedic Foundation for Animals (OFA) maintains a thyroid registry and issues a breed database number to all dogs found to have normal thyroid function at 12 months of age (based on measurement of free T_4 , TSH, and ATAs by an OFA-approved laboratory). Each dog must also be examined by a veterinarian. It is recommended that reexamination and retesting occur at 2, 3, 4, 6, and 8 years of age.

Anti- T_3 and T_4 Antibodies

Antibodies directed against T_3 and T_4 also occur in canine thyroiditis, although they are less prevalent than ATAs. Anti- T_3 antibodies are identified in approximately 30% of hypothyroid dogs, whereas anti- T_4 antibodies are reported in 15% of hypothyroid dogs. Although some euthyroid dogs may be positive for anti- T_3 and T_4 antibodies, in the presence of other equivocal results the presence of antithyroid antibodies increases the likelihood of hypothyroidism. Antibodies directed against T_3 and T_4 may interfere with hormone assays, leading to a spurious increase or decrease in the measured hormone concentration. In theory these antibodies could also increase a low T_4 concentration into the normal range and result in a false diagnosis of euthyroidism, although typically the measured T_4 concentration is above reference range.

Anti-thyroid antibodies do not interfere with response to L-thyroxine supplementation.

TREATMENT

Synthetic sodium L-thyroxine is the initial thyroid supplement of choice in canine hypothyroidism. Synthetic products (salts of T_3 or T_4) are more stable and better standardized for potency. Liquid formulations are now available and have similar bioavailability to tablets. L-thyroxine has a serum half-life of 12 to 16 hours, and peak concentrations are achieved at 4 to 12 hours after administration; however, there is wide interdog variability. Recommendations for therapy are to administer L-thyroxine initially at a dose of 20 mcg/kg twice a day (see Fig. 41-1). Many dogs will ultimately only require supplementation once a day; however, starting at a twice-daily dosage maximizes the chance of a good response. Once a clinical response is achieved, a trial with once-a-day therapy can be instituted. In dogs with concurrent heart disease, a sudden increase in the basal metabolic rate may lead to cardiac destabilization; thus the starting dose should be decreased by 50% and then adjusted on the basis of therapeutic monitoring. This is especially important for dogs with congestive heart failure in which hypothyroidism could reduce myocardial function but hyperthyroidism will increase cardiac demands.

Synthetic T_3 administration is only indicated in the few situations when T_4 supplementation has failed to achieve a response in a dog with confirmed hypothyroidism. This may occur because of impaired T_4 absorption from the gastrointestinal tract. T_3 supplementation is not recommended for initial therapy. Dogs receiving T_3 supplementation are more susceptible to iatrogenic thyrotoxicosis. Combination products that contain both T_3 and T_4 should be avoided for similar reasons. The plasma half-life of synthetic T_3 is 5 to 6 hours; thus it needs to be administered three times a day. The initial starting dose is 4 to 6 mcg/kg every 8 hours. Intravenous L-thyroxine at a dose of 4 to 5 mcg/kg every 8 to 12 hours appears to be safe and effective for treatment of dogs in thyroid crisis caused by myxedema coma (Pullen and Hess, 2006). Other aspects of treatment in affected dogs include passive rewarming, supportive care, and treatment of concurrent disease.

Improvement in activity level in dogs treated for hypothyroidism should occur within 1 week. Improvement in other clinical signs should be observed 4 to 6 weeks after initiation of therapy, although dermatologic abnormalities may take several months to completely resolve. Initially the appearance of the hair coat may worsen as hair in the telogen phase is shed.

Therapeutic Monitoring

Monitoring of serum T_4 concentration during therapy allows individualization of the dose and dosing frequency and is also useful in evaluating dogs that fail to respond to thyroid supplementation. Measurement of serum T_4 concentration should be performed after at least 1 month of therapy. A serum sample is taken *before and 4 to 6 hours after treatment* and submitted for measurement

of T_4 concentrations. Dosage and frequency of thyroid supplementation can then be adjusted appropriately (see Fig. 41-1). The trough sample concentration should be at the low end of the normal reference range, and the peak T_4 concentration should be within the upper end of the reference range or slightly above it (up to 6 mcg/dl is considered acceptable). If it is only possible to collect one sample, a post-pill sample should be collected. Concurrent measurement of TSH concentration during therapeutic monitoring may also be useful in dogs in which TSH was increased before treatment. Documentation of a normal TSH is evidence of adequate supplementation; however, because of poor sensitivity of canine TSH assays, detection of over-supplementation is not possible.

Poor Response to Therapy

An absent or inadequate response to therapy may be the result of incorrect diagnosis, poor owner compliance, inadequate dose of thyroid supplementation, poor oral absorption of thyroid supplement, or use of inappropriate formulation. Therapeutic monitoring allows differentiation of all these causes except incorrect diagnosis. Defective conversion of T_4 to T_3 and resistance of peripheral tissues to the action of thyroid hormone are theoretic causes of treatment failure that have not been documented in dogs.

CHAPTER 42

Obesity

ANGELA L. LUSBY, Knoxville, Tennessee
CLAUDIA A. KIRK, Knoxville, Tennessee

PREVALENCE AND RISK FACTORS FOR OBESITY

The incidence of obesity is reaching epidemic proportions worldwide, and the consequences of excessive body fat on overall health is a topic at the forefront of human medicine. Obesity in companion animal medicine has similar health impacts and should receive the same attention from practitioners as other chronic diseases. In dogs and cats a general definition for obesity is exceeding ideal body weight by 15% to 20% because of excess adipose tissue. Based on recent studies, approximately 35% to 40% and 25% to 35% of adult dogs and cats, respectively, are either overweight or obese, with informal surveys indicating that this number exceeds 50% in 2006. The percentage is even higher for middle-aged animals, reaching over 40% in both species.

Several risk factors are associated with obesity in dogs and cats. In both species the peak incidence occurs at middle age and is highly associated with gonadectomy. Several studies in cats suggest that weight gain after spaying or neutering is a combination of slower metabolic rate and increased food intake. The metabolic changes caused by gonadectomy in dogs are not clear, but increased food consumption with decreased activity levels are suggested mechanisms for weight gain. Gender can also influence weight gain, with spayed female dogs and neutered male cats having an increased risk for excess body fat. Breed also has a significant role in the development of obesity in dogs. In particular, the golden retriever, dachshund, Shetland sheepdog, Labrador retriever, cocker spaniel, and dalmatian are more likely to become overweight. Finally, environmental factors such as sedentary lifestyles and ad libitum feeding regimens contribute to both canine and feline obesity.

PHYSIOLOGY

Weight gain occurs when energy intake exceeds energy output. Certain diseases such as hypothyroidism can contribute to weight gain by decreasing the metabolic rate and energy output. However, most overweight dogs and cats do not have underlying thyroid disease, and weight gain is caused by excessive caloric intake with inadequate physical activity.

Until recently adipose tissue was thought to be passive and involved only in energy storage and insulation. However, the role of adipose tissue as an endocrine organ has since been established. Hormones and proteins secreted from adipose cells, termed *adipokines*, appear to have roles in appetite, inflammation, insulin sensitivity, and metabolism. To date over 50 adipokines have been identified; some of the most intensely studied examples are leptin, resistin, and adiponectin. Leptin levels increase with obesity, and leptin is thought to have an important role in maintaining satiety. Resistin also rises with obesity, but the role of resistin remains controversial. Unlike leptin and resistin, adiponectin decreases with fat deposition and appears to have beneficial effects on the cardiovascular system and insulin sensitivity.

Excessive adipose tissue has a myriad of effects on the body. The deleterious effects can be mechanical by compression of organs and excessive strain on joints or physiologic with alterations in metabolism and organ function. Obesity has also been implicated in the cause or progression of neoplasia, cardiorespiratory disease, urogenital disease, endocrinopathies, metabolic derangements, dermatologic disease, and orthopedic disorders (Box 42-1).

DIAGNOSIS OF BODY CONDITION

A variety of methods are available to evaluate the body condition of dogs and cat, but not all are practical or cost effective. Body condition scoring is a simple method for assessing a patient's body condition and correlates strongly with other techniques used to estimate body fat. Using visual observation and palpation, a body condition score is assigned using either a five- or a nine-point scale (Fig. 42-1). The choice of scale is based on personal preference since the scoring criteria are similar. The goal of assessing body condition is to estimate proportion of body fat, irrespective of weight; to help assess risk for obesity-related disease or physical dysfunction; and to monitor changes in body fat over time. Body condition scores can also be used to estimate a patient's percent body fat, which is useful for determining weight-loss goals (see Fig. 42-1).

TREATMENT

The concept behind the treatment of obesity is simple: decrease caloric intake and increase physical activity. However, management of real-life cases is rarely so straightforward. Practical issues such as dietary restrictions, owner compliance, and multiple-animal households can make the process of weight loss more challenging. It is important to take a thorough history before prescribing a weight-loss strategy to address issues early and minimize owner frustration. It is also important to have an accurate description of the current diet, including table scraps, to determine current caloric intake and to understand

Box 42-1

Diseases Associated With Obesity in Dogs and Cats

Endocrinopathies

- Hypothyroidism
- Hyperadrenocorticism
- Diabetes mellitus
- Insulinoma

Orthopedic disorders

- Osteoarthritis
- Cranial cruciate ligament rupture
- Intervertebral disk disease
- Humeral condylar fractures

Metabolic alterations

- Insulin resistance
- Glucose intolerance
- Hepatic lipidosis (cats)
- Hyperlipidemia/dyslipidemia

Cardiorespiratory disease

- Tracheal collapse
- Laryngeal paralysis
- Brachycephalic airway obstruction syndrome
- Dyspnea
- Hypertension

Dermatologic abnormalities

- Dry, flaky skin
- Feline acne
- Alopecia
- Seborrhea

Neoplasia

- Mammary
- Transitional cell carcinoma

Urogenital system

- Urolithiasis (calcium oxalate)
- Urethral sphincter mechanism incompetence
- Dystocia
- Urinary tract infection

Functional alterations

- Decreased immune function
- Increased anesthetic risk
- Heat intolerance
- Decreased life span

owners' perceptions and beliefs about food. Planning a weight-loss strategy has five main steps:

1. Estimate current body condition and body fat percentage (see Fig. 42-1)
2. Estimate ideal body weight; this estimation is often based on clinical experience; a weight history can also be useful to determine ideal weight since most animals are close to ideal at the onset of maturity (approximately 1 year of age).
3. Determine the current caloric intake through dietary history
4. Calculate desired caloric intake
5. Implement an exercise plan

5 pt scale	9 pt scale	% body fat	Body condition scoring	Dogs	Cats
1	1	≤5	Emaciated —ribs and bony prominences are visible from a distance. No palpable body fat. Obvious abdominal tuck and loss of muscle mass.		
2	2	6-9	Very thin —ribs and bony prominences visible. Minimal loss of muscle mass, but no palpable fat.		
	3	10-14	Thin —ribs easily palpable, tops of lumbar are visible. Obvious waist and abdominal tuck.		
3	4	15-19	Lean —ribs easily palpable, waist visible from above. Abdominal tuck present. Abdominal fat pad is absent in cats.		
	5	20-24	Ideal —ribs palpable without excess fat covering. Waist and abdominal tuck present in dogs. Cats have a waist and a minimal abdominal fat pad.		
4	6	25-29	Slightly overweight —ribs have slight excess fat covering. Waist is discernible from above, but not obvious. Abdominal tuck still present in dogs. Abdominal fat pad is apparent, but not obvious in cats.		
	7	30-34	Overweight —difficult to palpate ribs. Dogs: fat deposits over lumbar area and tail base. Abdominal tuck may be present, but waist is absent. Cats: moderate abdominal fat pad and rounding of the abdomen.		
5	8	35-39	Obese —ribs not palpable and abdomen may be rounded. Dogs: heavy fat deposits over lumbar and base of tail. No abdominal tuck or waist. Cats: prominent abdominal fat pad and lumbar fat deposits.		
	9	40-45+	Morbidly obese — Dogs: large fat deposits over thorax, tail base, and spine with abdominal distension. Cats: heavy fat deposits over lumbar area, face, and limbs. Large abdominal fat pad and rounded abdomen.		

Fig 42-1 Description of body condition scoring systems and their relationship to body fat percentage. (Illustrations from Drs. Foster and Smith, Inc.)

Choosing an Appropriate Diet

Weight-loss diets for dogs and cats typically fall into two categories: over-the-counter light and lean products or prescription weight-loss diets. Although over-the-counter products may be sufficient in animals that are mildly overweight, prescription weight-loss diets are recommended for substantial weight loss. Owners often ask if they can simply reduce the amount fed of the animal's current diet. Switching to a diet designed for weight loss is more desirable. Maintenance diets are calorically denser, with higher levels of fat than calorie-restricted diets. In addition, the components of maintenance foods are balanced to provide adequate amounts of nutrients when standard feeding guidelines are followed. When the

amount of a maintenance diet is significantly reduced below feeding recommendations, deficiencies in protein and other nutrients can occur. Diets formulated for weight loss are balanced to provide both adequate nutrients and energy restriction. In cases in which the diet cannot be changed because of medical conditions, the quantity of the current diet can be reduced, but review of total intake should ensure adequate nutrient intake.

Most canine weight-reduction diets rely on high levels of fiber, air, or moisture to reduce energy density. It has been proposed that high levels of fiber increase satiety by allowing the dog to ingest more food while receiving fewer calories. Although some evidence suggests that high levels of fiber do not affect satiety in dogs, other studies support the effect of diet bulk (i.e., fiber) in lowering total energy intake.

Following the trend in human dieting, low-carbohydrate, high-protein diets have also been proposed for use in dogs. Current evidence suggests limited benefit to using these diets for weight loss in dogs. In general, it appears that weight loss occurs with caloric restriction, regardless of the protein or fiber content. However, the proportion of fat loss over lean tissue loss is greater in dogs when fed high-protein foods compared to maintenance levels.

In recent years there has been much debate about the most appropriate diets for feline weight control. Cats are strict carnivores and naturally consume very high-protein diets. Therefore, many are advocating high-protein weight-loss diets for cats instead of more traditional high-fiber diets. Studies have shown that high-protein diets do appear to have beneficial effects on insulin sensitivity and diabetic control. However, a study evaluating only weight loss in cats did not detect any differences between high-protein and high-fiber diets, whereas the partitioning of weight loss, as in dogs, favored fat tissue loss when feeding low carbohydrate and high protein. For now, using high-protein, low carbohydrate or high-fiber diets for feline weight loss is a matter of personal preference. Further studies will be needed to truly determine if one diet is superior to another.

Estimating Desired Caloric Intake

As stated previously, obesity is the consequence of energy intake exceeding energy output. Energy output can also be called the daily energy requirement (DER). DER is made up of several components, but the resting energy requirement (RER) and the exercise energy requirement (EER) are the two largest contributors. The RER is the energy needed to maintain normal metabolic functions (e.g., blood flow, cellular metabolism, respiration) and is closely correlated with lean body mass. The RER typically accounts for 60% to 80% of the total DER. EER is the energy exerted through muscular activity and exercise and accounts for roughly 10% to 20% of DER in nonactive humans. Compared to lean mass, fat mass is metabolically inactive and contributes little to the RER. Therefore estimations of RERs should be based on ideal rather than current weight. RER can be estimated using the following formula:

$$\text{RER} = 70(\text{BW}_{\text{kg}}^{0.75})$$

If a scientific calculator is not available, the linear equation achieves similar results in animals over 2 kg: $\text{RER} = (30 \times \text{BW}_{\text{kg}}) + 70$. The DERs needed to achieve weight loss are then estimated using the RER. The result is the total number of calories that should be fed in a 24-hour period.

Canine DER for weight loss = 1 to 1.2 \times RER

Feline DER for weight loss = 0.8 \times RER

Careful monitoring of patients should occur during any weight loss program. The goal is to achieve 1% to 2% loss of body weight per week. Although the formulas above

are useful for initial estimations, some animals, especially cats, may require further restriction to achieve weight loss. Reducing energy by 10% of calories every 2 weeks until adequate weight loss is achieved may be required.

Role of Exercise

Increasing physical activity is an intuitive part of any weight loss program, yet exercise is often overlooked in companion animals. In dogs a 20- to 30-minute walk 3 to 4 days a week is a good method for burning calories. It may be necessary to address limiting medical issues such as joint disease or osteoarthritis in some dogs (see Section XII). Having owners play games such as fetch or hide-and-seek with toys or treats can also increase activity. It is important to discuss any limitations the owners have in exercising their pets and then offer creative, helpful suggestions. Creativity becomes even more important when trying to increase the physical activity levels of cats. Indoor cats lead more sedentary lives than outdoor cats, and special efforts must be made to increase their activity. Owners can begin by changing the cat's environment by providing more vertical space to explore with items such as window hammocks, platforms, and cat furniture. Barriers such as baby gates can also be used to force cats to exert more effort while moving around the house. Meals can be served on top of surfaces that require the cat to climb. Toys that hide kibble and require effort to extract the treat can occupy some cats. In addition, owner interaction in the form of play can be very effective. Even increasing play or exercise for just 10 minutes a day can be highly effective in promoting weight loss.

Future Role of Pharmacotherapy in Veterinary Obesity Management

Pharmacologic therapies for the treatment of obesity can target several areas. They can decrease energy consumption through modulation of satiety signals or blocking intestinal absorption, increase energy expenditure by increasing metabolic rates, or redistribute stored energy in adipose tissue to more metabolically active tissue such as muscle. Currently only two drugs are approved for weight loss in humans. Sibutramine (Meridia, Abbott) exerts anorectic effects by inhibiting serotonin/norepinephrine reuptake, and orlistat (Xenical, Roche Pharmaceuticals) increases fecal fat excretion. In dogs and cats drugs such as sibutramine that increase serotonin availability are associated with significant adverse side effects. Orlistat has not been studied in cats, but in dogs only modest weight loss was achieved and treatment complications included leakage of colonic contents with perianal soiling.

The control of satiety is a complex process. The hypothalamus is the main center of the brain that mediates satiety. Factors that signal the hypothalamus to increase or decrease food intake include nutrients, hormones, and intestinal peptides found in circulation and neurologic impulses from vagal and sensory nerves. The complexity surrounding the regulation of food intake provides many potential targets for increasing satiety. In the early 1990s an endogenous cannabinoid system was discovered that regulates synaptic neurotransmission and exerts effects on

*Body weight at estimated ideal.

many diseases and physiologic processes, including satiety, psychiatric disorders, and multiple sclerosis. A specific receptor in the cannabinoid system, cannabinoid-1 (CB-1) has been targeted for obesity treatment by the new drug rimonabant (Acomplia, Sanofi-Aventis), which is a CB-1 receptor antagonist. Rimonabant is currently in phase III clinical trials for humans. Unfortunately results in dogs and cats are not promising. Dogs appear to have transient weight loss that subsides after several weeks of therapy. In addition, side effects such as vomiting, diarrhea, and pruritus are significant at therapeutic doses. In cats CB-1 antagonists do not result in weight loss at tolerated doses.

Pharmaceutical induction of canine weight loss is now possible following the 2007 introduction of Slentrol (dirlotapide; Pfizer Animal Health) and Yarvitan (mitratapide; Janssen Animal Health). These drugs are classified as microsomal triglyceride transfer protein (MTP) inhibitors. Microsomal triglyceride transfer proteins are endoplasmic reticulum proteins expressed predominantly in intestinal and liver tissue where they play a pivotal role in the assembly of lipids to apoprotein B (apoB). Lipid assembly is required for export of lipoproteins across cell membranes and transport of lipids in the circulation. The MTP inhibitors for canine weight loss are selective for the intestine, thereby blocking MTP activity and the intraluminal transport of fat across the enterocyte. Turnover of lipid-laden enterocytes result in loss of fat (and calories) into the feces. More importantly, intestinal lipid accumulation appears to increase release of potent satiety signals from the gut (e.g., pancreatic peptide YY; PYY) and inhibition of voluntary food intake. Up to 90% of the canine weight loss has been attributed to appetite control. These drugs are an effective tool for canine weight loss. However, if feeding and exercise plans are not initiated, dogs will regain weight when treatment is stopped. The selectivity of MTP inhibitors varies by species. Dirlotapide

and mitratapide are not to be used in humans or cats due to the possible risk of hepatic lipid accumulation.

Canine Diabetes Mellitus

WILLIAM E. MONROE, *Blacksburg, Virginia*

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Diabetes mellitus in dogs is a persistent defect of carbohydrate metabolism associated with an absolute deficiency of insulin in nearly all cases. Therefore almost every affected dog will require administration of exogenous insulin for management of the disease. The underlying cause in dogs is poorly understood, but is likely multifactorial, including genetic predisposition; infectious, toxic, or inflammatory damage of the pancreatic islets with progressive immune-mediated destruction; or predisposing conditions such as natural or iatrogenic endocrine disorders, obesity, and hyperlipidemia that cause insulin resistance with subsequent β -cell exhaustion. The hospital prevalence in North American teaching hospitals seems to have increased between 1970 (19 dogs per 10,000) and 1999 (64 dogs per 10,000). Part but perhaps not all of this increase may be explained by a general increase in the age of hospital populations. Females, neutered or intact, and neutered males are overrepresented, although female predisposition may be declining. The peak age of occurrence is 7 to 11 years, with 70% of patients older than 7 years at the time of diagnosis. Diabetes occurs rarely in dogs younger than 1 year of age.

Absolute insulin deficiency associated with canine diabetes mellitus is also associated with an increase in glucagon concentration. Together these changes lead to hyperglycemia, both from increased hepatic production and lack of peripheral use. When blood glucose concentration exceeds the renal threshold (180 to 220 mg/dl), osmotic diuresis occurs, leading to secondary polydipsia. There is also fatty acid mobilization with consequent increased production of ketoacids by the liver because the peripheral tissues become energy starved. In addition, ketoacid production is increased because of the lack of the effects of insulin on lipoprotein lipase and hormone-sensitive lipase to facilitate the storage of fatty acids in adipocytes. As ketoacid production exceeds the quantity used for energy metabolism, acidemia occurs, and spillover of ketones into the urine contributes to polyuria. Without insulin the ability of cells to use glucose is markedly diminished. Furthermore insulin deficiency reduces fatty acid deposition in adipocytes and decreases the incorporation of amino acids to form protein. These metabolic abnormalities create a catabolic state with resultant weight loss despite adequate or excessive food consumption.

DIAGNOSIS AND MANAGEMENT PLAN

The diagnosis of diabetes mellitus is based initially on a combination of clinical signs that generally include polyuria and polydipsia, weight loss in spite of a good appe-

tite, and the demonstration of persistent hyperglycemia with glucosuria. It is not necessary to repeat blood and urine glucose testing to confirm the persistence of hyperglycemia if the clinical signs of polyuria, polydipsia, and or polyphagia have been noted. Ketonuria may be present in 66% of dogs with uncomplicated diabetes mellitus. Increased serum alkaline phosphatase, alanine transaminase, and hypertriglyceridemia are also common.

Once the diagnosis of diabetes mellitus has been established, it is important to determine if the dog has *complicated* diabetes (see Chapter 47). This is critical as diabetic ketoacidosis or hyperosmolar, nonketotic diabetes are complications that require aggressive in-hospital management. Conversely, uncomplicated cases are better managed as outpatients. The major clinical criteria for determining if a dog requires aggressive management relates to clinical findings; in other words, is the patient ill, anorexic, or vomiting or, conversely, is the dog eating and drinking well and exhibiting a generally healthy attitude. The dog that appears generally well and shows a good appetite can be managed as an uncomplicated diabetic even in the presence of ketonuria. Morbidity in these patients is rarely severe enough to require hospitalization and intensive care.

Before initiating therapy, it is also important to discuss the effort and cost of management of a diabetic dog with the owner and identify comorbid conditions. Lifestyle or financial circumstances may prevent some owners from successfully managing a diabetic pet. Foremost, it is important that the clinician have a clear understanding of the owner's lifestyle and daily schedule so that a feasible treatment and monitoring protocol can be developed. Additionally, many of these older dogs manifest concurrent disease that can affect control of the diabetes and also may influence the owner's decision to treat or not. Accordingly, a thorough medical evaluation should be conducted to identify concurrent diseases. In addition to the history and physical examination recommended studies include a complete blood count, serum chemistries (including canine pancreatic lipase immunoreactivity [cPLI]), urinalysis, urine culture, thoracic radiographs, and abdominal ultrasonography or radiography. It is not unusual for diabetic dogs to have clinically silent urinary tract infections, including a lack of pyuria in the sediment examination; thus it is important to culture the urine of all patients even if urinalysis results are unremarkable.

DIET, FEEDING SCHEDULE, AND EXERCISE

Diets that are high in fiber, low in simple sugars, and moderately restricted in fat and protein are recommended for diabetic dogs (also see Chapter 45). However, the most

important aspect of diet for diabetic dogs is that it be a balanced diet that the dog will eat consistently.

If dogs receive insulin twice daily, it is recommended to feed two equal meals at the time of insulin administration. Some clinicians recommend that the dog be fed before injecting insulin and withholding the insulin injection anytime the dog does not eat its entire meal. Although this may work well for a dog that is a gluttonous eater, it is less effective for finicky eaters or those dogs that eat small amounts throughout the day.

Even when insulin is given just once daily, it is still recommended that the dog be fed twice daily. The second meal should coincide with the glucose nadir (depending on when the owner can be home to feed) or alternatively should be presented 12 hours after the insulin injection. Feeding a larger portion of the daily diet around the time of the glucose nadir may lead to a less fluctuating glucose curve. However, if lente insulin given once daily provides adequate control, the glucose response can be improved in some cases by feeding the larger meal at the time of the insulin injection. This is because lente insulin contains 30% short acting-insulin (Semilente) and 70% long-acting insulin (Ultralente) and is absorbed in many dogs in a manner such that there are two peaks of insulin activity, with the earlier peak leading to the higher insulin concentration.

Exercise affects both the absorption of insulin and the metabolic use of glucose. Consequently, exercise levels should be kept constant with activity provided at the same times every day.

INSULIN THERAPY

As stated above, virtually all diabetic dogs require insulin therapy. Only one insulin product has recently been approved in the United States for use in dogs. Therefore in the past, veterinarians by necessity have relied on products labeled for human use. Current trends toward the use of recombinant human insulin and insulin analogs have further limited the number of products appropriate for canine diabetics. Additionally, many insulin products commonly used to manage diabetic dogs in the past have been removed from the market. Both recombinant human insulin (with one amino acid difference from canine insulin) and porcine insulin (with an identical amino acid sequence to canine insulin) have been advocated for canine diabetes because they may be less antigenic in dogs. The use of compounded insulin products is not recommended because of a lack of consistency and stringent control of the formulation.

The general recommendation for insulin treatment in dogs involves administration of an intermediate-duration-of-action insulin twice daily, or a long-duration-of-action insulin once daily. The only intermediate-duration products that are available currently are recombinant human neutral protamine Hagedorn (NPH) insulin and porcine lente insulin (Vetsulin, Intervet, Inc). An advantage of Vetsulin is that it is approved by the Food and Drug Administration for the dog. Since this product is produced and marketed by a veterinary company primarily for treatment of dogs, it should be available for many years. There is some experience with this product as it has been used in Canada and many European countries under the brand name Caninsulin for many years. Although it is not the identical product as the

previously utilized pure porcine lente insulin (previously marketed for humans by Eli Lilly), it is very similar, and likely can be used in a similar manner in dogs.

In a recent study of 53 diabetic dogs designed to determine the safety and efficacy of Vetsulin (Monroe et al., 2005), 66% of the dogs required injections every 12 hours for adequate control of blood glucose. Sixty days after the appropriate dose and schedule were determined, the median Vetsulin dose was between 0.75 and 0.78 U/kg per injection (range 0.28 to 1.4 U/kg) for dogs receiving insulin every 12 hours and 1.09 U/kg (range 0.43 to 2.18 U/kg) for dogs receiving insulin once daily. All 53 dogs were adequately controlled at the end of the dose determination period, and 75% remained adequately controlled 60 days later.

There is a long-acting protamine zinc insulin available for veterinary use (PZI VET, IDEXX Pharmaceuticals). This insulin product contains 90% beef and 10% porcine insulin. Currently this preparation is not recommended for use in dogs because beef insulin is more antigenic than human or porcine insulin. This may increase the production of antiinsulin antibodies, which can lead to poor glucose control in some dogs. However, it should be noted that beef:pork (90:10) insulins were used for years to manage diabetic dogs with few reported problems.

Insulin glargine (Lantus, Aventis) is a human insulin analog in which the amino acid asparagine has been replaced by glycine within the α -chain and two arginine molecules have been added to the C-terminus of the β -chain. In the vial it is in solution at a pH of 4.0, but the insulin solution forms crystals that are absorbed slowly when injected subcutaneously (SQ) into an environment with a pH close to 7.0. It cannot be mixed with any other insulin products. In humans it is intended to provide basal insulin levels over an extended period when administered once daily. Although there is very little information about the use of this product in dogs, it may be useful as a longer-acting insulin in patients for which NPH or lente insulins have too short a duration to provide adequate glycemic control with two daily injections.

Determining Insulin Dose and Frequency of Administration

In dogs with uncomplicated diabetes it is recommended to initiate treatment with an intermediate-duration-of-action insulin product such as recombinant human NPH or porcine lente (Vetsulin) at a dose of 0.25 U/kg every 12 hours SQ starting at time in the morning that will fit the client's schedule. Blood glucose is measured two or three times at 3-hour intervals during the first day to ensure that the dose is not so high as to create hypoglycemia. If the blood glucose drops below 100 mg/dl at any time during the first day, the dose should be reduced by 25%. Because it can take several days for the dog to adjust to any change of insulin dose or product type, it is sent home to receive insulin injections for 5 to 7 days before the first recheck to monitor the response to the insulin. In an attempt to prevent tissue irritation from injecting insulin at the same site while maintaining consistent absorption of insulin from each injection, it is recommended to alternate injections at approximately 1 to 2 inches on either side of the midline. The suggested level is over the thorax from just caudal to the scapulae to the last rib, alternating from

side to side. This allows for an injection site with similar blood supply, skin thickness, and muscular activity.

Since each dog may react uniquely to any insulin product, the appropriate dose and number of injections per day must be determined by monitoring the blood glucose response to the product (also see Chapter 46). This is accomplished by taking a careful history and performing a thorough physical examination, including body weight, to determine if clinical signs have resolved or are resolving. In addition, one should perform a glucose curve at 5- to 7-day intervals until the appropriate protocol is determined, which often takes 4 to 6 weeks. Performing one or two blood glucose measurements after the morning injection to titrate the insulin dose is inadequate and often leads to poor glucose control and hypoglycemia. To provide adequate information, the glucose curve should be performed after feeding the same food and giving the same insulin product and dosage at the usual times on the morning of the test. Blood glucose is determined every 2 hours for 10 to 12 hours, beginning either just before the dog is fed and given insulin or within 1 hour of doing so. Deciding to feed and give insulin to the dog at home before coming to the hospital depends on some practical factors: 1) the time in the morning that the dog is usually fed and treated, and 2) whether or not the dog is likely to eat normally in the hospital setting. It is best to keep feeding and insulin administration within 1 hour of the usual schedule while beginning the curve at a time that is practical for the owner and veterinarian.

Glucose concentration can be determined using a point-of-care analyzer or handheld glucose meter to reduce the amount of blood drawn and the associated trauma to the patient. Handheld glucose meters generally underestimate the serum or plasma glucose concentration by 10% to 15% compared to a reference laboratory.

Based on the results of the clinical response of the patient and the blood glucose curves, the insulin dose is adjusted by 1 to 5 U per injection, depending on the size of the dog and blood glucose concentrations measured every 5 to 7 days. The dose is adjusted to obtain a blood glucose nadir concentration of 80 to 150 mg/dl and to attempt to maintain the blood glucose concentration less than 250 to 300 mg/dl. It is important to determine the duration of insulin activity based on glucose curve results. To determine the duration of insulin activity, the blood glucose nadir must fall sufficiently (to the range of 80 to 150 mg/dl) so that glucose concentrations of greater than 250 mg/dl can be considered as representing near complete loss of the administered insulin effect. In addition, it is important that the blood glucose nadir concentration remain above 65 mg/dl; otherwise counterregulatory hormonal responses may stimulate blood glucose concentrations exceeding 250 mg/dl prematurely, before the true duration of insulin activity has been exceeded. If the blood glucose concentration just before the next scheduled insulin injection is less than 150 mg/dl and the glucose nadir was appropriate, the dog should be fed without giving the next injection of insulin, and the glucose curve continued until the blood glucose exceeds 250 mg/dl to determine if the duration of activity of the insulin product is longer than 12 hours. If the blood glucose exceeds 250 mg/dl within 1 to 2 hours of feeding without giving insulin, the duration of insulin activity is likely very close to 12 hours. Some dogs do not

have an increase in blood glucose for some time after the injected insulin has been completely metabolized unless they are fed to provide a glucose source. If the glucose rises after feeding without giving insulin, it is generally safe to continue giving the same dose of insulin every 12 hours.

If the duration of insulin activity is longer than 14 but shorter than 16 hours and an extended glucose curve and/or clinical signs indicate blood glucose concentration drops too low overnight, then administering a dose of the intermediate-duration insulin in the evening that is lower than the morning dose provides safe and adequate control in most cases. If the duration of insulin activity is longer than 16 hours, the dog may be adequately controlled with one daily injection of the product.

If the duration of action of an intermediate-duration insulin is longer than 16 hours but the dog continues to have clinical signs of polyuria and polydipsia, particularly during the night, a different intermediate-acting preparation could be tried every 12 hours, or a longer-acting product such as PZI or insulin glargine could be given once or twice daily. It cannot be overemphasized that when starting a diabetic dog on any insulin once daily, the duration of the response to that product must be determined by means of an adequate glucose curve. There is great variation among dogs in the duration of action of insulin products; for example, an insulin that is considered of long duration may have an effect of less than 12 hours in certain dogs. Treating with once daily insulin, but without adequate glucose monitoring, often leads to hypoglycemia. This is explained by the tendency to continue to increase the daily insulin dose in response to continued polyuria and polydipsia when the actual problem is not an inadequate dose but an inadequate duration of activity.

Longer-Term Monitoring of Insulin Therapy

Once the appropriate insulin preparation, dose, and dosing interval have been determined, it is appropriate to reevaluate the dog in 30 days. At that examination a history and physical examination should be conducted, and urine ketones, blood glucose curve, and perhaps fructosamine concentration measured. Thereafter rechecks every 3 to 6 months are appropriate unless the dog develops problems such as recurrence of polyuria or polydipsia, weight loss, signs of hypoglycemia, or another disease. The owner may be asked to check urine glucose and ketones periodically, but the dose of insulin should not be altered on the basis of urine glucose determinations alone. The presence of ketonuria, or of consistently high urine glucose, particularly if checked in the afternoon, should prompt reevaluation by the veterinarian.

Once an appropriate dose and schedule have been determined, it must remain consistent. Alternatively, the dose may be changed by the owner within a narrow, acceptable range set by the veterinarian. The client must understand that, as with humans, the true insulin need is likely to vary from day to day but the goal is to identify a dosage and schedule that will prevent clinical signs without episodes of hypoglycemia on most days. Realistic therapeutic goals are first to maintain the dog as an acceptable companion and pet and second to attempt to prevent formation of diabetic cataracts.

It has been well documented that fructosamine values in dogs that are well controlled can overlap with those that are poorly controlled and glucose curve values can vary from day to day. Therefore it is important not to rely on just one parameter to determine adequacy of glucose control or to change the insulin dose. If the glucose curve values do not seem to coincide with the history and physical examination results, the glucose curve should be repeated at the hospital, by the owner at home, or using a continuous glucose monitoring device while the dog is in the home setting. The clinical history and physical examination demonstrating resolution of polyuria and polydipsia; maintenance of body weight; normal appetite; and lack of clinical signs of hypoglycemia are generally the most reliable parameters for determining adequacy of glycemic control.

COMPLICATIONS AND PROGNOSIS

Hypoglycemia is one of the most serious complications of insulin therapy in diabetic dogs. Owners should be educated about the clinical signs of hypoglycemia, and should be instructed to feed a meal when signs of low blood glucose develop, assuming the dog is sufficiently aware to consume food safely. For dogs that are not fully conscious, the owner should be instructed to rub syrup or honey on the gingival mucosa in an attempt to revive the dog before calling the veterinarian.

Most dogs live for a few years with diabetes. The average survival may be approximately 3 years, but survival

likely depends on the age of onset, concurrent disease, ease of management, and owner commitment. Most dogs develop cataracts within 5 to 6 months of the diagnosis, and 80% develop cataracts by 16 months after diagnosis.

CHAPTER 44

Feline Diabetes Mellitus

JACQUIE S. RAND, *Queensland, Australia*

Diabetes mellitus is the second most common endocrinopathy in cats and affects approximately 1 in 50 to 1 in 400, depending on the population studied. Diagnosis of diabetes mellitus is based on finding persistently increased blood glucose concentration.

Management of diabetic cats depends on the stage of β -cell failure. In most cats diabetes is usually not diagnosed until relatively late in the disease process when extensive β -cell function has been lost. Diagnosis is typically made once blood glucose concentration is above the renal threshold and signs of polyuria, polydipsia, and weight loss are apparent. In contrast, in humans with type 2 diabetes, diagnosis is made earlier in the disease process. Cats and humans have a very similar range for normal blood

glucose concentration. However, in humans diabetes is defined as persistent blood glucose concentration above 126 mg/dl (7 mmol/L) because of the proven microvascular complications associated with higher blood glucose concentrations. Because of this difference in diagnosis and extent of β -cell failure, the majority of humans and the minority of cats can be managed satisfactorily with oral hypoglycemic drugs.

Based on data in other species, blood glucose concentrations below the renal threshold but persistently above normal (e.g., 180-216 mg/dl [10-12 mmol/L]) are likely associated with adverse effects such as glucotoxic damage to β -cells and in cats should be classed as diabetes. With the current availability of low-carbohydrate feline diets,

research is urgently needed to determine the most appropriate blood glucose concentration for institution of dietary management. Logically, if there are no contraindications such as azotemia, cats should be changed to a low-carbohydrate, high-protein diet whenever there is persistently increased blood glucose concentration (e.g., above 144 mg/dl [8 mmol/L]). These diets significantly reduce blood glucose concentrations compared with high-carbohydrate diets. Cats should then be monitored on a regular basis (e.g., every 3 to 6 months), and strategies introduced to limit weight gain and maintain optimum body condition.

PATHOGENESIS OF DIABETES IN CATS

To effectively manage diabetic cats, an understanding of the pathogenesis and main features of feline diabetes is required. The majority of owned cats in developed countries that develop diabetes likely have type 2 diabetes, which is characterized by a relative lack of insulin secretion and insulin resistance. Insulin resistance reduces the glucose-lowering effect of insulin. Diabetic cats are on average six times less sensitive to insulin than healthy cats, representing a similar magnitude of insulin resistance to that identified in humans with type 2 diabetes. Insulin resistance results from a number of mechanisms, and in most diabetic cats more than one mechanism is likely operating. A small percentage of cats have other specific types of diabetes resulting from B-cell destruction associated with pancreatitis and neoplasia, or have marked insulin resistance from excess growth hormone or corticosteroids.

Insulin Resistance

In humans the most important causes of insulin resistance are genotype, obesity, and physical inactivity. These same factors are also the most likely causes of insulin resistance in cats. It is important to be aware of these predisposing factors so that they are appropriately managed. This is vital in cats at risk of diabetes and also in cats in diabetic remission to ensure that they have the best chance of remaining in remission. Obesity markedly decreases insulin sensitivity in cats. An increase in body weight from an ideal weight of 4 kg to 6 kg halves insulin sensitivity in cats. Therefore management of body condition is an important part of therapy for prevention and management of feline diabetes. Physically inactive cats have been shown to be at risk of diabetes, and increasing physical activity improves insulin sensitivity in other species. One study in cats also found that active play for 10 minutes daily produced the same rate of weight loss as calorie restriction.

Genetic predisposition is likely a risk factor for insulin resistance and diabetes in cats. Lean cats with insulin sensitivity values below the median for the population were at three times greater risk of developing impaired glucose tolerance when they gained weight than cats with higher insulin sensitivity. Impaired glucose tolerance is the glycemic state between normal and diabetic. It is likely that these cats had underlying insulin resistance associated with genotype and, with time, obesity would result in diabetes in some. Burmese cats are at increased risk of diabetes in Australia, New Zealand, and the United Kingdom and appear to have underlying insulin resistance.

High blood glucose concentration also contributes to insulin resistance. In dogs it has been shown that this effect has a relatively short-term influence, with insulin resistance related more closely to glycemia over the previous 48 hours rather than over longer periods. This is relevant especially in the initial phases of treatment, and clinicians need to be aware that with decreasing blood glucose concentration insulin sensitivity is increased.

Impaired Insulin Secretion

Insulin secretion is decreased in feline diabetes through a number of mechanisms, some of which are reversible. Loss of β -cells in type 2 diabetes is thought to result from apoptosis triggered by chronic hyperfunction secondary to insulin resistance. β -cell loss also occurs as a result of islet amyloid deposition. Reversible suppression of insulin secretion occurs when blood glucose or lipid concentrations are high. This is called *glucotoxicity* and *lipotoxicity*, and both may act through similar intracellular mechanisms in the β -cell. With time chronic hyperglycemia irreversibly damages β -cells, and they are permanently lost, which can lead to insulin-dependent diabetes. Loss of β -cells also occurs through pancreatitis, and approximately 50% of diabetic cats have histologic evidence of pancreatitis. In most cats the severity of the lesion is not sufficient by itself to cause diabetes but potentially contributes to loss of β -cells. When insulin resistance is not involved, clinical signs of diabetes ensue once approximately 80% to 90% of β -cells are lost. If insulin sensitivity is reduced, clinical signs of diabetes occur earlier. If insulin sensitivity is reduced, clinical signs of diabetes occur earlier with smaller loss of B-cells. For example, with obesity-induced insulin resistance, cats need 30% more insulin to maintain fasting glucose concentration than when they were lean, and develop diabetes earlier with less B-cell loss. Veterinarians need to impress on owners the importance of attaining an ideal body condition in their diabetic cats or cats at risk of diabetes.

Diabetic Remission

Within days to months of beginning treatment with insulin, a proportion of diabetic cats are able to maintain euglycemia without therapy. This is called *diabetic remission*. The proportion of cats that achieve diabetic remission depends on how early tight glycemic control is instituted, on the type of therapy, and the underlying cause of their diabetes. Cats require functioning β -cells to attain remission. It is believed that reversal of glucotoxicity and lipotoxicity leads to diabetic remission. Therapies that provide the best glycemic control are likely to lead to the highest remission rates. Cats in remission may relapse in weeks to months, and it is important that they are carefully monitored and managed in remission. With early reinstitution of insulin therapy, many cats can again achieve remission.

MANAGEMENT OF DIABETES

The most important goals of therapy are to resolve clinical signs and avoid clinical hypoglycemia, which can be life threatening. The best way to resolve clinical signs is to achieve diabetic remission. Treatments available for

management of feline diabetes include dietary modification, insulin, and oral hypoglycemic drugs. The prevalence of diabetes is increasing as risk factors such as obesity and physical inactivity become more common. Management and prevention of diabetes need to also address these risk factors. Maintaining ideal body weight and avoiding drugs such as corticosteroids and progestins are important for maintaining remission.

Diet

Diet is an important component of therapy, and a low-carbohydrate diet is vital for cats achieving diabetic remission (also see Chapter 45). A high-carbohydrate diet (50% of energy from carbohydrate) can increase mean blood glucose concentrations from 4 to 18 hours after eating by 20% to 25% and peak glucose concentrations by more than 30% compared with a moderate-carbohydrate diet (25% energy from carbohydrate). Cats eating an ultra-low-carbohydrate diet (5% of energy) have even greater reduction in blood glucose concentration. Reducing carbohydrate content of the diet also decreases the demand on β -cells to secrete insulin. Cats in diabetic remission likely have reduced β -cell mass, and, from the limited testing reported, approximately 50% have impaired glucose tolerance. It is vital that these cats be fed diets that spare β -cell function. Feeding a low-carbohydrate diet once diabetic remission is achieved will likely prolong remission. To achieve and maintain remission, it is important to achieve an ideal body weight because of the negative impact of obesity on insulin resistance. Diet is also important for achieving weight loss. A minority of cats fed canned low-carbohydrate, high-protein diets self-restrict energy intake and lose weight spontaneously after their diet is changed. For the majority of cats, energy intake needs to be restricted to achieve weight loss. Physical activity promotes weight loss and improves insulin sensitivity in other species, independent of body weight. Encouraging owners to engage in active play with their cat is likely beneficial.

Insulin Therapy

Insulin therapy is the mainstay of therapy in diabetic cats. Veterinary insulin preparations available for maintenance treatment of diabetic cats include porcine lente insulin (40 U/ml; Caninsulin/Vetsulin, Intervet, Inc.), and protamine zinc insulin (PZI, 100 U/ml Shering-Plough and PZI Vet 40 U/ml IDEXX Pharmaceuticals). Human insulin preparations used for long-term maintenance of diabetic cats include neutral protamine Hagedorn (NPH), glargine, and detemir. Human lente and Ultralente insulin preparations have been removed from the market in most countries.

Glargine

Glargine and detemir are long-acting insulins with different mechanisms of action. Both insulins have been used in cats, but only glargine has been subject to a controlled trial. Anecdotal information in cats suggests that detemir and glargine have similar effects. Anecdotal information in cats suggests that detemir and glargine have similar

clinical effects. In a trial of 24 cats, eight of eight newly diagnosed diabetic cats treated with glargine and an ultra-low-carbohydrate diet (5% of energy from carbohydrate; Purina DM canned) achieved remission compared with three of eight for PZI and two of eight for porcine lente. Remission rates of greater than 80% to 90% often can be achieved using glargine combined with a low- or ultra-low-carbohydrate diet in newly diagnosed diabetic cats. This compares with 20% to 30% using other insulin preparations and a standard feline maintenance diet. One study reported 60% remission rates using PZI or lente insulin and a low-carbohydrate diet. Lower remission rates occur in long-term diabetic cats changed to glargine therapy. Diabetic remission is unlikely in cats that have been diabetic for more than 2 years.

Because of the huge advantage to the client and the cat in achieving diabetic remission, it is strongly recommended that the *first choice of insulin for diabetic cats be glargine*. If there is a legal requirement to first use a veterinary insulin product, PZI would be the first choice because it has longer duration of action than lente insulin. Lente insulin has too short a duration of action for optimal blood glucose control in cats. Using lente insulin, there is a period of at least 4 hours twice daily when there is no exogenous insulin action and high blood glucose concentrations ensue, often 360 mg/dl (20 mmol/L) or higher. Because the blood glucose concentration is very high, administering a potent insulin such as lente results in a rapid drop in blood glucose concentration. The hypothalamic neurons detect a falling blood glucose concentration and trigger counterregulatory mechanisms before hypoglycemia occurs. This is because these neurons control their intracellular glucose concentration by limiting glucose uptake when plasma glucose concentration is high. With a rapidly dropping blood glucose concentration, the hypothalamic neurons become hypoglycemic at relatively high blood glucose concentration. The resultant counterregulatory mechanisms are often triggered when blood glucose concentration is still above the normal range. Cortisol, epinephrine, and glucagon are released, producing insulin resistance and increasing blood glucose concentrations. The end result is further shortening of insulin action, which for some cats treated with lente insulin is only about 3 hours. It also results in insulin resistance, and the following insulin injections may result in little appreciable glucose lowering effect.

Recommendations for Using Glargine

Glargine is a long-acting insulin designed to provide basal insulin concentrations in humans with type 1 and 2 diabetes. Administration in humans is coupled with prandial administration of an ultra-short-acting insulin or oral hypoglycemic drug. In cats, because the postprandial period is so prolonged (12 to 24 hours) compared with humans, administration of an ultra-rapid-acting insulin at the time of eating is unlikely to be useful.

Glargine is produced by recombinant deoxyribonucleic acid technology using *Escherichia coli*. It is supplied as a clear, colorless solution of monomeric insulin with a pH of 4.0. When injected into the subcutaneous tissues with a pH of 7.0, glargine forms hexamers, and microprecipitates

deposit in the tissues. These slowly break down, releasing monomeric glargine into solution, which gives glargine its long duration of action. It is because of this mechanism of action that glargine cannot be diluted or mixed with other insulins. Glargine is available only at a concentration of 100U/ml, which makes accurate dosing a problem in cats, particularly when very low doses are being administered close to remission. Insulin syringes with 0.25-U or ¼ -U gradations, which are very useful for cats, are available in the United States.

Glargine has been used successfully in cats with a starting dose of 0.5U/kg BID if blood glucose is ≥ 360 mg/dl (≥ 20 mmol/L). The initial starting dose should not exceed 3U/cat BID. It is strongly recommended that glargine be administered twice daily in the first 4 months of therapy to maximize glycemic control and diabetic remission. Glargine administered once daily has been shown to be similar in effectiveness to lente insulin twice daily. In general the dose should not be increased in the first week, except if little or no glucose-lowering effect is still evident after the third day. In many cats the dose needs to be reduced in the first 7 days. It is important that if the dose is increased after the third day there is intensive glucose monitoring. Increasing the dose without monitoring can result in clinical hypoglycemia. It is recommended that close monitoring and adjustment of dose occur in the first month of treatment because many cats achieve diabetic remission within this time. It is prudent to keep the cat in the hospital and check blood glucose concentration for the first 3 days after institution of treatment to check for evidence of hypoglycemia. If this is not possible, closely monitor urine glucose concentration and water drunk as indicators of glycemic control. If a marked decrease in water drunk occurs in the first week or urine glucose becomes negative, recheck the cat because a lower insulin dose is likely indicated. If no monitoring of glucose, water drunk, or urine glucose concentration is possible, it is safer to begin with 1U/cat BID and increase dose weekly. Poor monitoring and inadequate tailoring of the dose to control hyperglycemia will delay or prevent diabetic remission.

It is recommended that cats be checked weekly in the first 4 to 8 weeks after institution of therapy and the dose be adjusted appropriately (Box 44-1). Glargine can be used in combination with regular insulin in treating ketoacidosis. Administer the usual starting dose of glargine subcutaneously twice daily and regular insulin intramuscularly at 1U every 2 to 4 hours, aiming to keep glucose between 145 and 250 mg/dL (8 and 14mmol/L). Regular insulin is required until appetite returns or dehydration is resolved, which is 24 to 48 hours in most cats.

Occasionally the dose of glargine needs to be increased to 5 or 6U/cat and rarely 10 U/cat twice daily over the first 1 to 2 months. In the majority of these cats, once glycemic control is achieved, the dose then needs to be reduced. Careful monitoring is required to prevent hypoglycemia. Rarely is hyperadrenocorticism or acromegaly a cause for treatment failure. When they are present, high doses of insulin are often required, especially with acromegaly, which may require extreme doses (>25 U/cat BID) to control blood glucose concentration. Do not delay insulin therapy and wait to determine if blood glucose normalizes after instituting therapy for underlying conditions contributing to insulin resistance. If blood glucose

Box 44-1

Current Recommendations For Adjusting Dose of Glargine in Diabetic Cats

1. Indications for increasing the dose of glargine

- If pre-insulin glucose concentration is ≥ 216 mg/dL (12mmol/L), then increase dose by 0.25-1 U/injection, depending on the degree of hyperglycemia.
- and/or
- If nadir (lowest) glucose concentration is ≥ 180 mg/dL (≥ 10 mmol/L), then increase dose by 0.5-1 U/injection.
- Only for well well-controlled cats after several weeks of therapy, increase dose if nadir ≥ 145 mg/dL (≥ 8 mmol/L).

2. Indications for maintaining the same dose

- If pre-insulin glucose concentration is ≥ 180 - <216 mg/dL (≥ 10 - <12 mmol/L)
- and/or
- If nadir glucose concentration is 90-160mg/dL (5-9 mmol/L).
- For well-controlled cats after several weeks of therapy, aim for a nadir of 72-145 mg/dL (4-8 mmol/L).

3. Indications for decreasing dose of glargine

- If pre-insulin glucose concentration is ≤ 180 mg/dL (≤ 10 mmol/L), decrease by 0.5-1 U/injection.
- If nadir glucose concentration is <54 mg/dL (<3 mmol/L), decrease by 1 U/injection.
- If clinical signs of hypoglycemia develop, administer 50% glucose IV bolus followed by 2.5% glucose infusion; then reduce dose by 50% and check for remission.
- If clinical hypoglycemia develops and is not severe, it often can often be managed by feeding the cat, preferably food containing a higher carbohydrate level, such as some dry foods. However, it must be palatable enough to eat. Most weight-reducing and renal diets are high-carbohydrate diets, as are many grocery lines of dry food.
- For cats with unexpected biochemical hypoglycemia (not clinical signs), some owners find that they can manage the hypoglycemia by delaying the insulin injection until blood glucose increases to 180 mg/dL (10 mmol/L) and then giving the same dose (the following dose of insulin may need to be reduced) whereas; others find it best to reduce the dose once glucose is 180 mg/dL (10 mmol/L), although this may result in subsequent hyperglycemia.

4. Insulin dose may be maintained or decreased, depending on the water drunk, urine glucose, clinical signs, and length of time the cat has been treated with insulin

- If nadir is 54-72 mg/dL (3-4 mmol/L)

Modified from Rand and Marshall: *Vet Clinics of North America* 2004. Reprinted with permission. Updated recommendations can be found at www.uq.edu.au/vetschool/centrecach.

concentrations are elevated (≥ 270 mg/dl; ≥ 15 mmol/L), insulin therapy should be instituted immediately to preserve β -cells and not be delayed until after other specific therapy.

Determining If Diabetic Remission Is Present

Many cats achieve diabetic remission within 2 to 4 weeks. It is strongly recommended that insulin therapy not be withdrawn prematurely. Cats with almost normal β -cell

function can tolerate 0.5 to 1U once or twice daily and rarely develop clinical hypoglycemia. If insulin therapy is stopped prematurely and hyperglycemia recurs, once insulin is reinstituted it can take weeks or months to achieve the same level of glycemic control. It is not recommended that insulin therapy be stopped within a minimum of 2 weeks of initiating treatment to facilitate β -cell recovery from glucotoxicity. Insulin dose should be decreased gradually based on dosing guidelines in Box 44-1. Once preinsulin blood glucose concentration is $\leq 180\text{mg/dl}$ ($\leq 10\text{mmol/L}$) and total dose is decreased to 0.5 to 1U BID, reduce the dosing frequency to once daily. If after 1 week preinsulin blood glucose is still $\leq 180\text{mg/dl}$ ($\leq 10\text{mmol/L}$) and nadir glucose concentration is in the normal range (72 to 126mg/dl ; 4 to 7mmol/L), discontinue insulin therapy and monitor blood glucose concentration during the day. If blood glucose rises above 180mg/dl (10mmol/L) within 12 to 24 hours, immediately reinstitute insulin at 1U once daily and wait a minimum of 2 weeks before again attempting withdrawal of insulin. If blood glucose concentration is less than 180mg/dl (10mmol/L), continue to withhold insulin, checking blood glucose every 3 to 7 days for several weeks, and carefully monitor the cat for signs of hyperglycemia (increasing thirst and glycosuria). Owners should diligently measure water drunk and monitor urine glucose concentration because increased thirst or glycosuria likely indicates relapse. If blood glucose is $\geq 180\text{mg/dl}$ (10mmol/L), insulin therapy should be reinstituted immediately. Some cats regain substantial β -cell function but require 0.5 to 1U of insulin every 2 to 3 days to maintain normoglycemia.

In general, blood glucose concentration following glargine administration does not change as quickly as with shorter-acting insulins such as lente; therefore monitoring every 4 hours is usually adequate. Critical time points to monitor are the blood glucose concentration just before each glargine injection (i.e., the preinsulin morning and evening glucose concentrations). For many cats the evening blood glucose concentration is lower than the morning concentration and is often the nadir glucose concentration. It is important to understand that occasionally blood glucose concentration can change rapidly, especially during the night, and can increase from 54 to 324mg/dl (3 to 18mmol/L) in 2 hours. It is not clear whether this rapid increase in blood glucose is mediated by counterregulatory hormones (Somogyi phenomenon) or reflects marked hepatic gluconeogenesis associated with negligible insulin concentrations. A rapid increase in blood glucose is more common when glargine is given once daily. Cats with low normal glucose concentration when last monitored in the evening may have very high blood glucose concentrations the next morning. In some cats decreasing the dose of glargine decreases morning blood glucose concentration, suggesting that the morning hyperglycemia may be the result of a Somogyi response. Somogyi phenomenon appears to be very rare in cats treated with glargine compared with shorter-acting insulins such as lente insulin. Cats treated with glargine appear quite susceptible to stress-induced hyperglycemia associated with hospital monitoring of blood glucose. If marked hyperglycemia is occurring in the hospital, it is critical that information be obtained on glycemic control at home before the hyperglycemia is attributed to treat-

ment failure. Measurement of water drunk, urine glucose concentration, or home monitoring of blood glucose concentration helps to clarify the level of glycemic control.

Biochemical Hypoglycemia

Cats treated with glargine often have biochemical hypoglycemia without clinical signs of hypoglycemia. Humans treated with glargine have significantly lower frequency of clinical hypoglycemia compared to those treated with NPH insulin. In cats clinical hypoglycemia also appears to be less common than when lente insulin is used. For cats with biochemical hypoglycemia (without clinical signs), some owners who are monitoring at home find that they can manage the hypoglycemia by feeding the cat and delaying the insulin injection until blood glucose increases to 180mg/dl (10mmol/L) and then giving the same dose; whereas others find it best to reduce the dose once glucose is 180mg/dl (10mmol/L), although this may result in subsequent hyperglycemia. If the first dose after biochemical hypoglycemia is not reduced, the second dose should be reduced unless the preinsulin blood glucose concentration is unusually high for that cat. Most cats showing signs of clinical hypoglycemia with glargine are in diabetic remission or will achieve remission within a few weeks.

Monitoring Glycemic Control

In addition to blood glucose measurements, water drunk and urine glucose concentration are invaluable indicators of glycemic control. Diabetic cats with exemplary glycemic control drink volumes similar to those of nondiabetic cats ($<10\text{ml/kg/24 hour}$ if eating canned food and $<60\text{ml/kg/24 hour}$ with dry food). When using glargine, in contrast to lente insulin, monitoring urine glucose concentration is less useful for detecting diabetic remission. This is because well-controlled diabetic cats that still require glargine to control blood glucose concentrations have negative or trace urine glucose concentration. However, urine glucose concentration is more useful for indicating a need for an increase in dose when using glargine. Fractious cats can be stabilized using urine glucose concentrations and water drunk alone, although glycemic control is usually not as good as when combined with blood glucose monitoring; therefore diabetic remission may be delayed or not achieved.

Storage of Glargine

Although the manufacturer recommends discarding glargine within 4 weeks of opening, an open vial of glargine can usually be kept for 6 months or more if *refrigerated*. The manufacturer's recommendation is based on the risk of bacterial contamination with multiple-use vials. Vials that develop any cloudy discoloration should be discarded immediately. This may represent precipitation or bacterial contamination.

Oral Hypoglycemic Agents

Oral hypoglycemic drugs act either by stimulating β -cells to secrete insulin, increasing insulin sensitivity, or by reducing glucose absorption from the gastrointestinal

tract. Glipizide is the most commonly used oral hypoglycemic drug in cats and acts by stimulating β -cells. It should not be offered as a first line of therapy because of the poorer control of blood glucose concentration and the subsequently lower rate of diabetic remission. However, it can be lifesaving for cats when the owner would elect for euthanasia if insulin injections were the only available treatment. Glipizide may be used instead of insulin in cats that have insufficient β -cell function to achieve remission but require only minimal doses of insulin to control hyperglycemia.

Acarbose inhibits brush-border glycosidase activity in the intestine and reduces postprandial blood glucose concentrations. Changing to an ultra-low-carbohydrate diet has a greater glucose-lowering effect than administering acarbose. However, cats that need a reduced-protein diet (high-carbohydrate) for control of azotemia might benefit from the addition of acarbose at 12 to 25 mg/cat twice daily at the time of eating. It is minimally effective if the cat is eating multiple meals daily. Acarbose should be administered twice daily, even if the cat is only fed once daily.

In summary, management of diabetic cats is optimized by using glargine administered subcutaneously twice daily,

combined with a low-carbohydrate, high-protein, feline diabetes diet and obesity management. Using this protocol to keep maximum blood glucose <200 mg/dL (<11 mmol/L), can result in diabetic remission in approximately 90% of newly diagnosed diabetic cats.

CHAPTER 45

Diet and Diabetes

DEBRA L. ZORAN, *College Station, Texas*

Diabetes mellitus in dogs and cats is a complex, multifactorial disease that results in insulin deficiency or a dysfunctional response to insulin. The disease affecting dogs is primarily one that results in the complete loss of β -cell function caused by destruction of these cells. In contrast, the disease in cats is quite different and is similar to the obesity-related diabetes associated with glucose toxicity and insulin resistance that is seen in adult humans. Nevertheless the end result in both forms of diabetes is hyperglycemia with associated abnormal lipid and protein metabolism, resulting in a catabolic state sometimes termed *starvation in the face of plenty*.

Insulin therapy is the mainstay of treatment for both diabetic dogs and cats (see previous chapters), but, because diabetes is a disease of disordered metabolism, nutritional therapy is a key component of the management of these patients. The goals of dietary therapy in any diabetic dog or cat are broad based and include the following: (1) to achieve and maintain optimal body condition;

(2) to provide a nutritionally complete, balanced, and palatable food that is readily consumed (so intake is predictable); (3) to provide nutritional support for any concurrent diseases requiring nutritional modification; (4) to maintain consistency in the timing and type (e.g., ingredients and calories) of food to assist in achieving optimal glycemic control; and finally (5) because the primary determinant of postprandial glycemia is starch, to control the amount and types of dietary starch present in the diet. Unfortunately, because of the paucity of well-designed dietary studies in diabetic dogs and cats, dietary recommendations cannot be based on research alone. Further, recent work has uncovered some important differences between dogs and cats in the most effective dietary management strategies for this disease. This chapter reviews the most relevant aspects of nutritional management of diabetes, the major differences between dogs and cats, and the role of specific nutrients and supplements in the management of diabetes.

DIETARY MANAGEMENT OF CANINE DIABETES MELLITUS

Dogs with diabetes typically are presented for examination because of polyuria, polydipsia, polyphagia, and/or weight loss; and many diabetic dogs have a thin body condition at the time of diagnosis. Thus the goal of achieving optimal body condition in a diabetic dog requires a dietary strategy that will not only assist in the control of postprandial glycemia but will also allow the dog to regain its normal body weight (BW). However, some diabetic dogs will be obese or of normal body condition; in these dogs the dietary strategy is still focused on achieving optimal body condition, but the type and amount of diet may be somewhat different than that for a dog that is very thin and needs to gain weight. One key point is that there is no single dietary strategy that works for all canine diabetics; thus clinicians must tailor their dietary recommendations to fit the specific needs of the individual dog.

Dietary Fiber

For many years diets containing increased amounts of dietary fiber have been recommended for dogs with diabetes because they improve postprandial glycemia presumably by delaying gastric emptying, slowing carbohydrate digestion and absorption, and altering gut hormones. However, dietary fiber is a term that encompasses a wide variety of complex carbohydrates that have widely varying effects in the gastrointestinal (GI) tract. Thus it is necessary to understand how dietary fiber is characterized and how these characterizations affect the ability of the fiber to affect glycemia in dogs.

Generally fiber is characterized by its degree of solubility, which also generally reflects its degree of fermentability (i.e., how completely the intestinal bacteria can break it down) and its properties in water (e.g., intestinal juice). Highly soluble fibers such as guar gum have a great water-holding capacity and form a viscous gellike solution in the lumen of the intestine. Normal dogs fed diets high in soluble fibers have more rapid glucose absorption because of increased intestinal glucose transport, increased glucagon-like peptide-1, and increased insulin secretion. In normal dogs this type of fiber lowers circulating glucose levels in glucose tolerance tests, but it is unknown whether these same effects occur in diabetic dogs.

Studies in nondiabetic dogs have evaluated the effects of diets containing different fiber types (highly fermentable, poorly fermentable or insoluble, and mixed-fiber types) to further clarify these issues. In these reports there was no significant difference between the effects of diets on oral glucose tolerance testing; serum triglyceride levels; or the cholesterol content of high-density lipoproteins, low-density lipoproteins, or very low-density lipoproteins. The only significant difference created by the diets was that total serum cholesterol concentrations were lower in dogs fed the diets containing mixed fiber.

Studies in diabetic dogs suggest that diets high in insoluble or mixed fiber may be associated with improved glycemic control. Insoluble-fiber diets appear to exert little physiologic effect on the canine GI tract compared to soluble-fiber diets and are not fermented by the bacterial flora;

therefore these diets are tolerated in higher levels with fewer side effects (e.g., diarrhea, flatulence). In studies comparing a mixed-fiber diet to a lower-fiber maintenance diet, there was significantly improved glycemic control in the group of diabetic dogs fed the mixed-fiber diet. However, regardless of the type or concentration of high-fiber diet fed or the duration of time over which the dogs were monitored, there was no significant difference in the daily insulin requirement or fasting triglyceride levels in diabetic dogs.

Finally there is a highly variable difference between dogs in their response to dietary fiber—in other words, there does not appear to be a uniform effect of fiber in all diabetics, and the effect of a type or amount of fiber in a diabetic dog is not predictable. A recent investigation in diabetic dogs compared a canned, high-fiber, moderate-starch diet to one that contained a moderate amount of fiber and starch but an increase in dietary fat. In these stable diabetic dogs there was no significant difference between the diets in insulin requirements or glycemic response.

Thus the decision to use a diet with increased dietary fiber in the therapy of a diabetic dog should be based on individual circumstances since there is no clear indication that these diets are beneficial in all cases. However, in dogs that may need to lose weight or those that are having poor glycemic control with a normal maintenance diet, diets containing increased insoluble or mixed fiber are reasonable choices. If the dog does not tolerate or will not eat a diet with increased amounts of fiber, the clinician should choose a maintenance or weight-reduction diet containing lower fat and high complex carbohydrates. Table 45-1 illustrates different diets, both fiber-containing veterinary diets and non-fiber-containing diets that may be used in diabetic dogs.

Dietary Carbohydrates, Fat, and Protein

The glycemic index classifies food based on its potential to increase blood glucose following absorption from the GI tract. To make diets that result in a more manageable postprandial blood glucose concentration, the glycemic index of the starch must be considered in diabetic dogs. In healthy dogs the amount of starch in the diet is a major determinant of the glycemic index, no matter what type of dog food is tested. In one study of healthy dogs, rice-based diets resulted in significantly higher postprandial glucose levels, while sorghum-based diets (especially barley) resulted in the lowest glycemic response. However, predicting the glycemic index of food is not based solely on the type of starch present in a diet, but on the matrix in which the carbohydrate is found, the type of processing the carbohydrate has undergone, and the total amount of carbohydrate consumed. Unfortunately, there are little data about the responses of diabetic dogs to different diets and different types of carbohydrates; thus it is difficult to make specific evidence-based recommendations for these dogs with diabetes. However, because highly digestible diets designed for GI disease often contain rice-based carbohydrate sources, these diets may not be ideally suited for diabetic dogs.

Diabetic dogs also have abnormalities in lipid metabolism secondary to the lack of insulin production. These changes include hypertriglyceridemia; hypercholesterolemia; and increases in lipoproteins, chylomicrons, and free fatty acids. In contrast to humans, who have

*Based on current product guides.

increased risk of cardiovascular disease and stroke, the major consequence of hypertriglyceridemia in dogs is the increased risk of pancreatitis, which clearly complicates the management of diabetes and increases the risk for secondary complications and morbidity. In most diabetic dogs the lipid values improve with the administration of insulin and by feeding a diet containing lower fat and higher fiber content. Current recommendations by nutritionists suggest feeding a diet that contains less than 30% of metabolizable energy from fat; however, there are very little published data on the influence of dietary fat or the optimal level of fat in dogs with diabetes.

In humans with diabetes, omega-3 fatty-acid supplementation has been recommended to reduce serum lipid levels, blood pressure, and platelet aggregation—all benefits that are important to reduce the risk of stroke and cardiovascular disease. However, in some humans with diabetes, consumption of increased amounts of omega-3 fatty acids results in increased blood glucose and an overall reduction in glycemic control. The effects of omega-3 fatty acids have not been adequately evaluated in dogs with diabetes; thus whether or not these same effects occur in dogs is not known.

Finally, L-carnitine is a conditionally essential vitamin-like nutrient that has an essential role in fatty acid metabolism. Dog with poorly controlled diabetes are prone to ketogenesis, weight loss, and altered fat metabolism—all factors that can be attenuated by improved lipid metabolism that may occur with supplementation of carnitine. The amount of carnitine that is needed to achieve this effect in dogs with diabetes is not clear, but in one report as little as 50ppm added to a canine diet improved lipid parameters in normal dogs.

Protein catabolism occurs when insulin concentrations are low or ineffective. Catabolism of muscle proteins is a protective mechanism designed to supply substrate (amino acids) that can be used for gluconeogenesis. Thus in unregulated diabetics, in diabetics that are not eating well, or in those being fed inadequate protein in the diet, muscle proteins are used. To prevent this loss of essential tissue, it is necessary that both an adequate quality and quantity of protein be supplied in the diet of diabetic dogs. In general, diets for diabetic dogs should contain a highly digestible (85% to 90%), high-quality protein (18% to 25% on a dry-matter basis) to reduce muscle catabolism. Such diets also provide adequate protein for maintenance and repair but do not appear to increase the risk of diabetic nephropathy.

Micronutrients

When a complete and balanced diet is fed in appropriate quantities for a dog's BW and condition, there is no need for additional vitamin and mineral supplementation in the majority of diabetic dogs. However, in many diabetic dogs that are not consuming a balanced diet (e.g., those consuming homemade or single-item diets) or in those that have uncontrolled diabetes, the risk of development of a micronutrient imbalance is increased.

The macrominerals most likely to be affected in diabetic dogs are potassium, magnesium, and phosphorus. In most dogs with adequate glycemic control that are consuming appropriate amounts of an adult maintenance food, either no macromineral imbalance occurs, or it self-corrects. Appropriate monitoring of electrolytes is an important

aspect of clinical evaluation of any diabetic, but especially in any dog that is not well controlled or is ill.

The importance of micronutrients in diabetics has been a topic of considerable interest in a variety of species for many years. The most important micronutrients in diabetes are zinc, chromium, selenium, copper, and manganese. Of these nutrients the essential role of zinc in the synthesis, storage, and secretion of insulin is clearly established; however, the exact mechanisms underlying altered zinc metabolism in diabetes in dogs have not been identified; thus specific recommendations for supplementation are difficult. Further, excesses of zinc can be quite detrimental and can cause complications such as gastritis and gastric ulceration, copper deficiency, and hemolytic anemia. The same ambiguity exists for the use of chromium in diabetic dogs. Chromium is essential for normal carbohydrate and lipid metabolism, and supplementation in humans with diabetes improves insulin sensitivity and overall control; but few studies have been performed in dogs with diabetes, and in one study no increase in glycemic control was observed.

Currently the best approach in diabetics is to feed a diet that has microminerals supplied according to the AAFCO recommendations for adult maintenance (see Appendix), and, if the dog is unwilling to eat this type of diet, a standard adult human vitamin-mineral supplement (1 tablet/dog/day) containing a United States Pharmacopeia (USP) label can be administered safely to prevent development of a micronutrient deficiency.

Food Type and Feeding Plans

As a general rule, most diabetic dogs, regardless of diet chosen, can be well managed with feeding a consistent diet at consistent times with concurrent administration of an appropriate amount of exogenous insulin. And, because there is no clear evidence that specific diets in diabetic dogs are essential to good glycemic control, the first rule of thumb is that the nutritional requirements of any concurrent disease in the diabetic dog should take precedence when choosing a diet. The next most important issue of diet selection is palatability to ensure that the dog will consistently and predictably consume the diet.

Both canned and dry foods are acceptable food types for diabetic dogs; however, because dry foods empty the slowest from the stomach, they have a somewhat greater effect in decreasing postprandial hyperglycemia than canned foods. Nevertheless, if the dog will more consistently consume the diet if it contains some canned food or if the dog needs the added water in its diet, canned foods are a completely acceptable diet for diabetics. Soft, moist foods should be avoided entirely because they contain large amounts of simple sugars (e.g., dextrose, fructose, sucrose, cane molasses) that are highly digestible and result in a large increase in blood sugar. In general, highly digestible foods (diets with greater than 90% digestibility) designed for GI disease may result in greater postprandial hyperglycemia; thus they are likely not the best diets for diabetic dogs. Conversely, diets with less than 80% nutrient digestibility and low fat concentrations may not be sufficient to help a thin diabetic regain lost BW.

Finally, it is ideal to choose a diet that has a fixed formula (as opposed to an open formula) so that there are fewer variations in the diet formulation that can affect the individual

Table 45-2

Calculating Calories

	Equations for Calculating Caloric Intake
Canine RER: ideal BW	$70(BW_{kg})^{0.75}$ or $45-50 \times BW_{kg}$
Canine MER: ideal BW	$125(BW_{kg})^{0.75}$ or $BW_{kg} \times 60-70$
Feline RER: ideal BW	$70(BW_{kg})^{0.75}$ or $40-45 \times BW_{kg}$
Feline MER: ideal BW	$90(BW_{kg})^{0.75}$ or $BW_{kg} \times 50-60$
Weight loss	Calculate calories for ideal BW (or a target below obese weight); if the number of calories is not less than what is currently being consumed, reduce intake by 10%-20%; assess in 2-4 weeks and readjust so that weight loss of 1%-2% per week is achieved

BW, Body weight; MER, maintenance energy requirement; RER, resting energy requirement.

response. Open-formula diets are those found in a typical grocery store or pet specialty supply stores, the formulation of which changes with market prices. Thus the glycemic index changes as the formulation of the open formula diet changes over time, which may result in a variable insulin response.

Once the diet is chosen, the next most important aspect of dietary management is to impress on the owner the importance of feeding consistent amounts of food at consistent times. Ideally diabetic dogs should be fed one half of their total daily energy requirement at a specified time in the morning at time of insulin administration. Then the second half of the dog's energy requirements should be given at the evening meal, approximately 12 hours later, coinciding with the evening insulin administration.

Calculation of energy requirements for diabetic dogs should be based on maintenance energy needs of the dog's ideal BW (Table 45-2). However, if the dog fails to gain weight despite an appropriate amount of insulin and food, an increase in the energy density of the food or increased daily caloric intake will be required. A final key point for a successful dietary management strategy in the dog is simply to monitor the BW and glycemic control and adjust the diet as needed but to maintain as much consistency as possible not only in the food type but also in the timing and amount.

DIETARY MANAGEMENT OF FELINE DIABETES

As in diabetic dogs, dietary therapy is a very important aspect of successful management of the diabetic cat. However, unlike the dietary therapy of dogs in which a diet containing increased dietary fiber and complex carbohydrate is recommended, management of feline diabetes requires a completely different strategy. There is now strong evidence showing that a diet containing high protein and low concentrations of carbohydrate is the most effective approach. In addition, because many feline diabetics are obese and have obesity-induced insulin resistance as part of their disease, dietary management of obesity is an essential aspect of therapy of this disease.

Thus, although dietary therapy of feline diabetes has similar goals to that in dogs, the approach is quite different.

Dietary therapy of feline diabetes has three major goals: (1) to correct or normalize BW (e.g., for the majority of cats that means to achieve weight loss); (2) to minimize the stimulation of pancreatic β -cells by glucose; and (3) to stimulate endogenous insulin secretion by feeding a diet high in arginine (a potent insulin secretagogue) and other amino acids.

Obesity is a major medical problem in the domestic feline population, with as many as 25% to 35% of cats in the United States being either overweight (15% to 20% over ideal BW) or obese (>20% over ideal BW). Obesity-induced diabetes currently is believed to be the most common form of diabetes in cats; thus both from the perspective of prevention as well as therapy, weight management is the first and possibly the most key aspect of dietary therapy. To induce weight loss in cats, a dietary strategy must be embraced that includes the following: (1) feed a diet high in protein to reduce muscle wasting and prevent the lipid and protein metabolic derangements that occur during calorie restriction; (2) feed a diet that is reduced in energy (both fat and carbohydrates) to stimulate fat mobilization; (3) adjust the food consumption to BW and response to food reduction; and finally, (4) consider supplementation with L-carnitine (a vitamin-like supplement that increases fat oxidation and maintenance of lean muscle tissue). A number of diets may be acceptable for this purpose, but the goal should be to have fat less than 4 g/100 kcal, starch less than 5 g/100 kcal, and protein content greater than 10 g/100 kcal. Diets with this profile stimulate loss of fat tissue and at the same time preserve lean muscle tissue (which is lost in cats fed lower-protein diets that are highly energy restricted).

The other essential aspect of achieving weight loss is to control energy intake. In most obese cats this means that meal feeding will be required to be able to provide the specified calories needed to achieve restriction. Maintenance energy needs for most indoor neutered cats are estimated to be 45 to 50 kcal/kg/day. However, to achieve weight loss the caloric intake may have to be more restricted, with a reduction in calories from the target goal of 10% to 40% being required in some cats. However, weight loss must be monitored carefully so that the loss does not exceed 1% to 2 % per week or hepatic lipidosis will occur. Many canned diets have a high-protein, low- to moderate-fat, low-carbohydrate profile and provide a way to control calories by volume; thus they are a good dietary choice for a feline weight-loss program. One of the most difficult aspects of

any weight-loss program is controlling intake while feeding both protein and volume to provide satiety. Because caloric intake can be easily and specifically controlled, protein levels are often high, and the added water increases volume, canned foods are a highly desirable option for weight loss. Table 45-3 illustrates the caloric differences among several high-protein, low-carbohydrate canned and dry diets and other diets that are fed to cats for weight loss.

The second goal of dietary therapy of feline diabetes is to control systemic blood glucose levels and reduce the perpetuation of the phenomenon of glucose toxicity occurring in the pancreatic β -cells. Before our understanding of the importance of high-protein, low-carbohydrate diets in cats with diabetes, diets high in fiber and carbohydrates were recommended for dietary management. However, feeding these diets led to high postprandial blood glucose concentrations, glucose toxicity, and ultimately reduced insulin secretion by the β -cells. Because the overall strategy in feline diabetics is unique (i.e., to achieve clinical diabetic remission and normalization of β -cell production and release of insulin), the dietary strategy first has to be aimed at reduction of postprandial blood glucose levels by feeding low-carbohydrate diets. In one study of newly diagnosed diabetic cats, cats placed on insulin and a high-protein, low-carbohydrate diet were four times more likely to achieve clinical remission; and, in cats that did not achieve remission, the amount of insulin required to control their diabetes was reduced by half. In addition to the amount of carbohydrate present in the diet, the type of carbohydrate source also appears to be important in cats, as it is in dogs. However, studies in diabetic cats comparing these diets to low-carbohydrate diets are lacking.

The third major aspect of dietary therapy of feline diabetes, which is to stimulate insulin secretion, is also achieved by feeding a high-protein, low-carbohydrate diet. In cats arginine and other amino acids are potent insulin secretagogues. Even in cats with glucose-induced hyposecretion of insulin, insulin secretion in response to the presence of arginine is normal to increased. Feline diets that are rich in animal source proteins contain abundant arginine, which contributes to endogenous insulin secretion in the diabetic cat and subsequently may help lead to diabetic remission.

In addition to high-protein, low-carbohydrate diets, dietary management of diabetic cats requires some consideration of their eating habits and the potential for hypoglycemia as a result of return of β -cell function. Unlike dogs, cats with diabetes on high-protein, low-carbohydrate diets do not need to match feeding with insulin admin-

Table 45-3

Feline Diabetic Diet Comparisons*

	Protein (% As Fed)	CHO (% As Fed)	Fat (% As Fed)	Calories (kcal/Cup or Can)

*Based on product guides.

istration, especially if the insulin glargine is being used. This is because postprandial hyperglycemia is minimal and instead blood glucose is prolonged after a meal because of the cats' unique glucose metabolism. Blood glucose levels in both normal and diabetic cats rises slowly and steadily after a meal and stays elevated for several hours, making timing of insulin administration to coincide with a postprandial glucose peak unnecessary. Diabetic cats that are not obese may be fed ad libitum to mimic the natural feeding pattern of the cat, which also reduces the risk of hypoglycemia should their own insulin secretion resume. However, an obese diabetic cat must be meal fed; preferably these cats are fed several small meals spread over 24 hours to provide calorie control to initiate weight loss and to provide an energy source should the cat attain diabetic remission. Calorie restriction is necessary in an obese diabetic cat to achieve weight loss; however, it is also important to be cautious because an increase in caloric needs for the diabetes may result in too rapid weight loss.

Because diabetic remission is an important goal, especially in newly diagnosed obese or previously obese cats, frequent monitoring (both of weight loss and glycemic control) and access to small amounts of food is the best strategy. The specific techniques used to monitor successful control of blood glucose in feline diabetics are beyond the scope of this paper but represent an essential aspect of diabetic management in cats (see Chapter 44). However, with appropriate use of diet in the management of feline diabetes, the goal of successful control, which may include clinical remission of the diabetes, can be achieved.

CHAPTER 46

Diabetic Monitoring

CLAUDIA E. REUSCH, Zurich, Switzerland

The aim of therapy in diabetic pets is to eliminate the clinical signs of diabetes mellitus, prevent short-term complications (e.g., hypoglycemia and ketoacidosis) and enable a good quality of life. It is not necessary to establish normal or near-normal blood glucose levels as it is in humans, for whom it is well known that good glycemic control significantly reduces the risk of life-threatening chronic complications (e.g., nephropathy and cardiovascular disease). These complications require many years to develop and are considered rare in diabetic dogs and cats. Most diabetic pets are doing well if the blood glucose concentrations (BGCs) are kept between 5 and 15 mmol/L (90 to 270 mg/dl) throughout 24 hours.

Management of diabetic dogs and cats relies on the owner's observations of clinical signs and on periodic evaluation by a veterinarian. The latter includes assessment of the owner's observations, measurement of body weight, and determination of blood glucose and serum fructosamine concentrations. Traditionally blood glucose measurements and generation of serial blood glucose curves were almost always performed in veterinary hospitals because most owners were unable to collect venous blood samples. Recently methods have been developed to collect capillary blood samples from the pet's ear that allows owners to measure BGCs at home. Home monitoring of blood glucose has displaced the measurement of urine glucose nearly completely in the clientele in our practice.

MONITORING IN THE HOSPITAL

Frequency of Reevaluations

After diagnosis of diabetes mellitus, the owner should be informed that it usually takes 2 to 3 months until stable glycemic control is achieved (see Chapter 43) and that lifelong regular reevaluations in the hospital are required. The exception to this guideline is animals (usually cats) that develop remission of their diabetes (see Chapter 44). Initially frequent reevaluations should be scheduled. With time, intervals between rechecks can be extended. In our hospital reevaluations are suggested at 1, 3, 8, and 12 weeks after diagnosis and then at intervals of approximately every 4 months.

Serum Fructosamine

Fructosamine measurements are widely used as an indicator of glycemic control in diabetic dogs and cats. Measurement is done in serum using commercially available test kits adapted to autoanalysis. Storage at 25°C for 5 days does not cause a significant change in fructosamine concentrations, allowing shipping of serum samples. Since fructosamine is the product of an irreversible reaction between glucose and the amino groups of plasma proteins, it is assumed that its concentration reflects the mean BGC of the preceding 1 to 2 weeks. Serum fructosamine concentration is not affected by short-term increases of blood glucose (approximately less than 4 days); therefore it is also a valuable tool to differentiate between diabetic and stress hyperglycemia in cats. Reference ranges differ slightly among laboratories but usually are somewhere around 200 to 360 $\mu\text{mol/L}$.

In the vast majority of newly diagnosed diabetic dogs and cats, fructosamine levels are greater than 400 $\mu\text{mol/L}$, but they may be as high as 1500 $\mu\text{mol/L}$. Normal fructosamine levels may be seen in animals with very short duration of diabetes mellitus. Fructosamine may also be normal in animals suffering from certain concurrent diseases. It has been shown that hypoproteinemia, hyperlipidemia, and azotemia in dogs and hypoproteinemia and hyperthyroidism in cats can decrease the fructosamine concentration. In these cases fructosamine measurements should not be used for the diagnosis or the long-term management of diabetes mellitus.

In all other cases it is helpful to measure fructosamine concentrations during routine reevaluations. The parameter is independent of stress and lack of food intake, which are both major influencing factors for blood glucose measurements in the hospital. Fructosamine concentrations increase when glycemic control worsens and decrease when glycemic control improves. It should be noticed that differences between two consecutive measurements have to exceed 50 $\mu\text{mol/L}$ to reflect a clinically significant difference in glycemic control.

As mentioned earlier, normoglycemia is not a treatment goal in veterinary medicine, and even well-controlled diabetic dogs and cats are slightly-to-moderately hyperglycemic throughout the day. Consequently fructosamine usually does not become completely normal during therapy. In contrast, the finding of a normal fructosamine level (in particular fructosamine levels in the lower half of the refer-

ence range) should raise concern for prolonged periods of hypoglycemia caused by insulin overdose. In cats in which fructosamine levels decrease into the normal range during therapy, the possibility of diabetic remission has to be considered. Fructosamine levels between 360 and 450 $\mu\text{mol/L}$ usually suggest good control, levels between 450 and 550 $\mu\text{mol/L}$ suggest moderate control, and levels greater than 600 $\mu\text{mol/L}$ suggest poor metabolic control. In the latter situation fructosamine measurement does not help to identify the underlying problem. All reasons for poor regulation have to be considered, including insulin underdosage, too short duration of insulin effect, diseases causing insulin resistance, and the Somogyi phenomenon.

Over the years, we and others have sometimes seen discrepancies between fructosamine on one hand and clinical sign and blood glucose on the other hand. Although high fructosamine levels suggested poor control, the lack of clinical signs and glucose level within the desired range pointed to good control. The reason for the discrepancy remains ambiguous in most instances, but it is possible that there are individual differences with regard to the extent of protein glycation. In those cases the assessment based on clinical signs should be given priority over assessment of fructosamine.

In animals with diabetic ketoacidosis, dehydration, acidosis, and other unidentified factors may influence fructosamine concentrations. Therefore fructosamine levels measured at the time of admission may differ considerably from the fructosamine concentration measured a few days later after successful therapy. It is advisable to repeat the measurement at the time of discharge and to use this level as a reference point for future measurements.

Glycated Hemoglobin

Glycated (glycosylated) hemoglobin has been used in human medicine since the 1970s and is regarded as the cornerstone of assessment of glycemic control in all major clinical trials. Comparable to fructosamine, it is formed by nonenzymatic, irreversible attachment of glucose to a protein amino group. Glucose first enters red blood cells and then interacts with amino groups of the globin chain of the hemoglobin. Although glycation kinetics is relatively complicated, it is commonly assumed that glycated hemoglobin reflects the average BGC over the life span of the erythrocytes, which is 100 to 120 days in dogs and 70 days in cats. Currently glycated hemoglobin is only rarely used as a long-term parameter in veterinary medicine. The main explanation for this situation pertains to the numerous assays available each measuring different components of hemoglobin; therefore results may not be comparable among laboratories. Furthermore, many of those assays do not provide valid results in dogs and cats.

Blood Glucose Measurements and Serial Blood Glucose Curves

Single blood glucose measurements are usually insufficient to assess glycemic control. Exceptions to this rule are dogs and cats with unremarkable history and physical examination and a serum fructosamine between 360 and 450 $\mu\text{mol/L}$. In these cases the finding of a BGC between

180 and 270 mg/dl around the time of insulin injection would support the assumption of good glycemic control and may render further blood glucose measurements unnecessary. Evaluation of a serial blood glucose curve (BGC) is mandatory in the initial phases of diabetic regulation and in animals with persistence of clinical signs, ongoing weight loss, and fructosamine greater than 500 μ mol/L. It is the BGC that provides guidelines for making rational adjustments in insulin therapy.

We usually recommend that feeding and insulin injection be done at home and that the animal be presented to the hospital as soon as possible thereafter. If technical difficulties are suspected, owners are asked to bring the animal to the hospital before the insulin application and to perform the whole administration procedure under the supervision of a veterinarian or a technician. Blood samples are then taken every 1 to 2 hours throughout the day until the next insulin injection in both cases.

BGCs enable the assessment of insulin efficacy, the glucose nadir, the time of peak insulin effect, the duration of the effect of insulin, and the degree of fluctuation in BGC. The most important parameters are insulin efficacy, glucose nadir, and duration of effect. Insulin efficacy, which is the difference between the highest and the lowest glucose concentration, has to be interpreted in the light of the highest BGC and the insulin dosage. A relatively small difference (e.g., 50 mg/dl) is acceptable in an animal in which the highest glucose concentration is less than 200 mg/dl; however, the same difference is not acceptable if the highest glucose level is greater than 300 mg/dl. Similarly the same difference (e.g., 100 mg/dl) may indicate insulin efficacy in an animal receiving a small dose of insulin (< 0.5 U/kg) but may point to insulin resistance if the insulin dose is high (>1.5 U/kg). In addition to insulin resistance, technical problems with the insulin administration procedure, stress hyperglycemia in the cat, and the counterregulatory phase of the Somogyi phenomenon also have to be considered.

After insulin effectiveness is confirmed, the glucose nadir should be interpreted and should ideally be between 90 and 140 mg/dl. A nadir less than 80 to 90 mg/dl can be seen with insulin overdosage, excessive overlap of insulin actions, lack of food intake, and strenuous exercise. In cases in which overdosage is identified, the insulin dosage should be reduced by 10% to 50%, and excessive overlap of insulin action may require a change to an insulin with shorter duration of action. If the nadir is greater than 160 to 180 mg/dl, insulin underdosage, stress hyperglycemia, the counterregulatory phase of the Somogyi phenomenon, and technical problems of the owners have to be considered. If the animal is already treated with high insulin doses, insulin resistance also may be possible. It is very important to identify the exact cause because treatment decisions differ and may be completely opposite of one another. For example, insulin underdosage should be treated by increasing the insulin dose by 10% to 25%, whereas the Somogyi phenomenon would be treated by decreasing the dosage by at least 50%.

Careful evaluation of the other parameters of glycemic control such as clinical signs and serum fructosamine is mandatory. In addition, it may be necessary to assess the owner's insulin administration technique. It should

be remembered that the counterregulatory phase of the Somogyi phenomenon may last up to 72 hours. Therefore several BGCs may be required to demonstrate a decrease of blood glucose to less than 60 mg/dl (or a very rapid decrease regardless of the nadir), followed by an increase in blood glucose to a concentration greater than 300 mg/dl within a 12-hour period following insulin administration.

Duration of insulin effect is evaluated if the glucose nadir lies in the desired range of 90 and 140 mg/dl and if there has not been a very rapid decrease of blood glucose after insulin injection. The duration is defined as the time from insulin injection through the glucose nadir until the BGC exceeds 250 to 270 mg/dl. If the duration of insulin effect is less than 8 to 10 hours, animals usually show clinical signs of diabetes mellitus. In contrast, if the duration is longer than 14 hours, the risk of developing hypoglycemia or the Somogyi phenomenon increases.

Problems Encountered With Monitoring Blood Glucose in the Hospital

Interpretation of BGCs generated in hospitalized animals may be difficult because of the potential influence of stress, abnormal housing conditions (e.g., lack of exercise), and decreased food intake on BGCs. A recent study by Fleeman and Rand (2003) showed that there is a large day-to-day variability when BGCs were performed on consecutive days in diabetic dogs. In addition, BGCs are time-consuming and expensive; therefore they are often not performed as frequently as required. Many patients would benefit from more frequent blood glucose determinations. For example, short-notice adjustments of the insulin dosage are necessary in diabetic patients with infections (increased dose) or at times of increased physical activity (mostly decreased dose). Close monitoring of BGC is also indicated in diabetic patients that are treated for a concomitant disease such as hyperadrenocorticism or hypothyroidism. Similarly, intact bitches may require adjustments of the insulin dosage at the transition from one stage of the cycle to another. Because of the abolition of the resistance to insulin associated with these conditions, the required insulin dosage may have to be reduced drastically to prevent life-threatening hypoglycemia. It is difficult to manage these cases without frequent blood glucose determinations.

MONITORING AT HOME BY THE OWNER

Frequency of Monitoring

Owners should assess their animals with regard to the clinical signs of diabetes mellitus on a daily basis. Body weight should be taken at least once a week. It is important that the owner be familiar with the clinical signs of the most important complications of diabetes mellitus (i.e., hypoglycemia and diabetic ketoacidosis). Today measurement of blood glucose is also feasible for owners and may be recommended for many owners.

Home Monitoring of Blood Glucose

Problems with diabetic control in people are similar in principle to those encountered in veterinary medicine.

Many of these issues have been largely eradicated since the late 1970s with the introduction of self-monitoring of blood glucose (SMBG) concentration. For SMBG humans obtain a drop of capillary blood by pricking a fingertip with a lancing device. The drop is then placed on a test strip, and the glucose concentration is measured using a portable glucose meter (PBGM). During the last few years similar methods for monitoring BGC have been developed for dogs and cats. The method used in Zurich is performed with a lancing device creating a negative pressure (Microlet Vaculance, Bayer Diagnostics, Zurich, Switzerland). Capillary blood is obtained from the inner aspect of the pinna, and BGC is determined with a PBGM. The method is relatively inexpensive, fast and easy to perform, and can be used by owners of diabetic dogs and cats to determine BGC and to generate BGC at home. Other techniques for blood sampling such as the marginal ear vein technique have also been described by Thompson and colleagues (2002).

Since their introduction, the quality control of PBGMs has been a frequent topic of discussion in human medicine. Studies have shown that accuracy can vary greatly but in general tends to be poor for very low as well as for very high glucose concentrations. Factors with a possible effect on the results of glucose measurements include variation in hematocrit, altitude, environmental temperature and humidity, hypotension, hypoxia, and triglyceride concentrations. It has become difficult to maintain the overview for the accuracy of all available PBGMs because new devices are frequently being developed by various companies, all of which claim to be smaller in size, faster in action, and easier to handle than their predecessors. Because PBGMs are usually made for use in humans and accuracies differ, quality control studies before their use in dogs and cats are extremely important. However, overall performance of these systems depends not only on analytic performance of the meter and quality of the test strips but also on the skills of the user.

For pet owners, home monitoring (HM) of blood glucose can constitute a challenge; therefore it is important to minimize technical difficulties as much as possible. Owners should be provided with a PBGM that is simple to operate. In our experience, the Ascensia Elite or the latest generation Ascensia Contour (both made by Bayer Diagnostics) are very easy to operate. Both meters have no buttons to press, turn on automatically when the test strip is inserted, and require a very small amount of blood, which is automatically aspirated into the reaction chamber after contacting the test strip. For the Ascensia Contour the measurement range is 10 to 600 mg/dl, the results are displayed within 15 seconds, and the last 240 measurements are stored. An additional advantage is the very low amount of blood (0.6 µl) required for blood glucose measurement. For more than 6 years, we have been involved in HM of diabetic dogs and cats, and the results have been extremely positive. The majority of owners are very interested in measuring blood glucose in their pets, and about 70% have been capable and willing to perform HM on a long-term basis.

A number of steps should precede the introduction of HM. The first step is a definitive diagnosis of diabetes mellitus. Additional tests to diagnose concurrent diseases may

be indicated at this point. The owner then receives detailed information about various aspects of diabetes mellitus and careful instruction on injection technique, and the concept of HM is mentioned for the first time. This consultation takes approximately 45 minutes. The second step consists of reevaluation of the patient after 1 week. Observations made by the owner are discussed, a clinical examination is performed, and fructosamine concentration and a 12-hour BGC are generated in the hospital. Treatment is adjusted if necessary. At the time of discharge, the importance of the BGC in the control of the disease is emphasized. In addition, the advantages of HM for owner and pet are discussed, and the owner is informed that this procedure can be started after the next reevaluation.

The third step follows approximately 3 weeks after the diagnosis has been made. The owner is now provided the opportunity to learn the technique of HM. This requires a minimum of 30 minutes and consists of repeated demonstrations of the use of the lancing device and the PBGM. The owner then performs the technique several times in the pet. He or she is also taught how to calibrate the PBGM (if needed), how to check the meter's accuracy using the control strips, and how to record the blood glucose values on forms prepared by our clinic. HM is not started before the third week after a diagnosis of diabetes mellitus. This allows the owner to become familiar with the disease and to gain experience with the injection of insulin. However, introduction of HM is delayed to a later date if the owner does not seem ready for it.

Once the owner is comfortable with the procedure, we request that a fasting BGC be determined twice weekly and a BGC once monthly. The former serves to detect morning hypoglycemia, in which case the owner is instructed to call us. For determination of a BGC, the BGC is measured before the insulin injection (fasting) and every 2 hours thereafter. Since all our diabetic animals receive insulin BID, the BGC is performed over a 12-hour period. The owner sends the results of the BGC, and appropriate changes in treatment are discussed, if necessary, on the telephone. The assessment of the BGC generated at home follows the same rules as for the BGC generated in the hospital. Periodic reassessments of the entire procedure in the hospital are mandatory. For the first 2 months the patient is reassessed at least once a month; after that time, the frequency of rechecks is reduced to approximately every 4 months.

It is important that owners have ready access to veterinary support, if required. The majority of our clients call for advice one or more times, especially after the start of HM. Sometimes support via telephone is not sufficient, and additional explanation or demonstration of the technique must be provided. By watching an owner perform the procedure, a veterinarian can identify and correct errors immediately. The most frequently encountered technical problems included inadequate formation of a blood drop caused by excessive pressure of the finger behind the ear while lancing the ear, repeated depression of the plunger instead of allowing the negative pressure to slowly build up, and failure to fill the test strip to the mark. Therefore these procedural steps require explicit explanation and demonstration. Handling the PBGM usually is not a problem for owners, and most report that

their pet tolerates blood collection well. The skin puncture does not seem to be painful, and the puncture sites are barely visible, even after numerous blood collections.

Recently Casella and colleagues (2003) and Casella, Hässig, and Reusch (2005) compared BGCs generated at home with those generated in the hospital with regard to treatment decisions. In about 60% of cases treatment decisions would have been the same; in about 40% treatment decisions would have been different. In the 40% in which treatment decisions would have differed, only 3% of dogs and 8% of cats would have had treatment decisions that would have been contrary (e.g., increase versus decrease of insulin dosage); in the others, although the decisions would have been different, they would have had little clinical consequence. Our most recent studies indicate that there also is a lot of variability if BGCs are performed at home on consecutive days. Therefore single curves may not reflect the true glycemic situation regardless of whether they are generated in the hospital or at home. However, one of the major advantages of HM is that it enables frequent generation of BGCs, which may be of particular importance in animals that are difficult to regulate. In those cases more than one BGC can be performed at home before a decision is made concerning therapy.

Long-term compliance of pet owners is good; many perform HM for several years. According to a recent retrospective survey in cat owners, only a minority adjusted insulin doses independently, and most of them called the hospital for advice. All cat owners believed that HM provides major advantages over in-hospital monitoring.

It has been argued that pet owners who are able to perform HM would visit the hospital less frequently. However, our observations over the last years do not support this. Frequency of reevaluation does not differ among pets with or without HM.

HM is a valuable additional tool in the management of dogs and cats with diabetes mellitus. One of its major advantages is that blood glucose can be measured more frequently than when it has to be done in the hospital. In animals that are difficult to regulate, several BGCs generated at home can be interpreted before a treatment decision is made.

Monitoring of Urine Glucose

Until blood glucose measurement became possible, urine glucose testing was the main method of assessing glycemic control at home. Glucose is freely filtered at the glomerulus and actively resorbed at the proximal tubule. The resorption capacity for glucose is limited; and, when the BGC exceeds the so-called renal threshold (approximately 180 mg/dl in dogs and approximately 300 mg/dl in cats), urine glucose excretion is roughly proportional to hyperglycemia. However, measurement of urine glucose may be misleading for several reasons: (1) the result does not reflect the actual blood glucose but is an average over the time of urine accumulation in the bladder; (2) a negative urine test does not differentiate between hypoglycemia, normoglycemia, or mild hyperglycemia;

and (3) hydration status and urine concentration may affect the result. It is also possible that in individual dogs and cats the renal threshold may increase or decrease as is known to occur in humans. Therefore severe hyperglycemia may exist without glucosuria, and glucosuria may occur with a normal BGC.

We do not adjust insulin dosages on urine glucose measurements, nor do we allow owners to do this. Owners who are unable to measure blood glucose but still want monitor may be advised to use urine glucose measurements in all urine samples voided throughout 1 day per week. Persistent glucosuria would suggest inadequate glycemic control and the need for thorough evaluation in the hospital. In susceptible animals (repeated bouts of diabetic ketoacidosis), we recommend that owners check the urine for ketone bodies on a regular basis to detect impending or actual ketoacidosis.

Complicated Diabetes Mellitus

DEBORAH S. GRECO, *St. Louis, Missouri*

Complications arising from the diabetic state are the most common reason for mortality from diabetes mellitus; the majority of diabetic animals die of renal failure, infections, or hepatic/pancreatic disease rather than from diabetes mellitus itself. Most cats presented for diabetic ketoacidosis (DKA) have concurrent diseases, including hepatic lipidosis, cholangiohepatitis, pancreatitis, chronic renal failure, urinary tract infection, and neoplasia. Many diabetic dogs exhibit elevated liver enzymes, lipemia, and bacteriuria. Diabetic dogs often suffer from conditions such as dermatitis or otitis externa, hyperadrenocorticism, acute pancreatitis, tumors, and hypothyroidism.

Frequently there is an underlying stressful event that precipitates the shift from diabetes mellitus to DKA or nonketotic hyperosmolar diabetes mellitus. The precipitating event may be a urinary tract infection; other viral or bacterial infection; or an inflammatory disorder such as pancreatitis, pyelonephritis, cholangiohepatitis, inflammatory bowel disease (IBD), eosinophilic granuloma complex, prostatitis, pyometra, upper respiratory infection, or pneumonia. Other concurrent diseases may include renal insufficiency or failure, hepatic lipidosis, neoplasia, or congestive heart failure. Recent drug therapy may also precipitate a crisis, especially administration of corticosteroids or progestagens. Therefore further diagnostic testing of the diabetic patient that presents in a crisis is essential, particularly use of abdominal radiography and/or ultrasonography, as well as thoracic radiography and/or echocardiography, if indicated. Additional testing for concurrent endocrine diseases such as hyperthyroidism in cats and hypothyroidism and hyperadrenocorticism in dogs may also be indicated but should be postponed until some control of the diabetes mellitus is achieved, inasmuch as uncontrolled disease may affect the results of the tests.

Concurrent conditions may be difficult to distinguish from complications of diabetes mellitus. Generally diabetic complications fall into the following six major categories: (1) diabetic nephropathy, (2) diabetic neuropathy (peripheral and autonomic), (3) susceptibility to infections (e.g., urinary, pulmonary), (4) hepatic and pancreatic disease, (5) diabetic ocular problems (cataracts), and (6) hypoglycemic complications.

DIABETIC NEPHROPATHY

Diabetic nephropathy occurs in approximately 40% to 50% of insulin-dependent humans with diabetes; however, the complication develops over a long period of time, often as long as 20 years. Although dogs may suffer from diabetic nephropathy, as evidenced by proteinuria and systemic hypertension, cats are more likely to suffer the

long-term consequences of diabetic nephropathy because of a longer life span. However, the exact incidence of diabetic nephropathy in cats remains unknown. Diabetic nephropathy, like other diabetic complications, is associated with poor glucose regulation.

The earliest sign of diabetic nephropathy is microalbuminuria followed by increases in urine protein-to-creatinine ratio. Systemic hypertension, caused by activation of the renin-angiotensin system, may contribute to glomerulosclerosis and further renal damage. Azotemia is a late consequence of diabetic nephropathy but may be partially or completely reversible with good diabetic regulation. Hyperglycemia increases glomerular filtration rate and renal plasma flow and may increase binding of plasma proteins to glomerular basement membranes. Elevation of tissue polyol concentrations, a sequelae of hyperglycemia, contributes to renal dysfunction. Thickening of the glomerular basement membranes and glomerular hypertension may also contribute to renal problems. Early identification of diabetic nephropathy may result in reversal of glomerular damage if glycemic control improves.

Diabetic nephropathy occurs in some cats with type 2 diabetes mellitus, as evidenced by increased presence of microalbuminuria. Poorly regulated diabetic cats are more likely to exhibit proteinuria than well-regulated diabetic cats, and a significant relationship of systolic pressure to microalbuminuria has been noted in cats with diabetes.

Early identification of diabetic nephropathy may allow for proper treatment and potential reversal of glomerular damage. Improvement of glycemic control is the key therapeutic intervention; however, wide swings in blood glucose should be avoided. Equally as important in controlling hyperglycemia is minimizing the insulin dosage. Large fluctuations of blood glucose contribute to glycosylation of tissues, including glomerular tissue. Proper treatment of type 2 diabetes mellitus in cats using a low-carbohydrate diet, oral hypoglycemic agents, and basal insulin (e.g., glargine) may help prevent progression of diabetic nephropathy. Dietary protein should not be restricted until significant azotemia is present. High-protein diets have been associated with improved diabetic regulation; therefore restriction of protein leads to loss of diabetic regulation in cats with advanced renal disease and diabetes.

DIABETIC NEUROPATHY

Because of the difficulty in achieving adequate glycemic control with insulin therapy in cats with type 2 diabetes mellitus, diabetic neuropathy is a common attending condition in diabetic cats. Most diabetic cats suffer from a clinical or subclinical form of diabetic neuropathy, as can

be shown via neurologic examination, impaired motor and sensory peripheral nerve studies, and nerve biopsy (e.g., myelin degeneration in the Schwann cell).

Clinical signs include severe manifestations such as plantigrade stance when standing and walking. Cats are unable to communicate sensory deficits or abnormalities; however, sensorimotor neuropathy, characterized by conduction deficits and increased F wave and cord dorsum potential latencies in both pelvic and thoracic limbs, has been documented in diabetic cats. Furthermore, nerve structural abnormalities such as splitting and ballooning of myelin and demyelination, indicative of Schwann cell injury, is common in cats with neuropathy. Axonal degeneration is less common, developing in severely affected cats.

INFECTION

Impaired immune function secondary to diabetes mellitus increases the risk of infections. In one study half of diabetic dogs had occult urinary tract infections without evidence of pyuria. Urine from diabetic animals should always be cultured to determine the presence or absence of infection. If infections are detected, a long course (i.e., 6 to 8 weeks) of an appropriate bacteriocidal antibiotic is indicated. Good choices for antibiotic therapy that penetrate into the urinary tract include the penicillins, cephalosporins, quinolones, and potentiated sulfas. The latter two antibiotics should be used in male dogs to ensure penetration into the prostate.

Other common sites of infection in diabetic animals include the liver (e.g., infectious cholangiohepatitis); lung, skin, and ears (e.g., yeast and bacterial infections); small intestine (e.g., bacterial overgrowth); and teeth (e.g., dental abscesses). In cats the stress of a condition as common as dental disease can lead to the release of counterregulatory factors. With resolution of the disease, insulin requirements may decline to the point at which the patient is no longer diabetic. Therefore dental prophylaxis should be considered standard treatment in diabetic cats.

HEPATIC DISEASE

Concurrent gastrointestinal disease is very common in diabetics, particularly diabetic cats. In the study by Crenshaw and Peterson (1996), 39 of 42 cats presented for DKA had concurrent diseases, including hepatic lipidoses, cholangiohepatitis, pancreatitis, chronic renal failure, urinary tract infection, and neoplasia. In another survey of concurrent disorders in 221 diabetic dogs, over 70% had elevated liver enzymes (Hess and Ward, 2000). Alanine aminotransferase and aspartate aminotransferase are most commonly affected; these increase secondary to hypovolemia and poor hepatic blood flow and subsequent hepatocellular damage. Further increases in serum alkaline phosphatase concentration may occur if pancreatitis and secondary cholestasis ensue. Concurrent hepatopathies are often present in patients with DKA, but evaluation is complicated by the effect of both the diabetes mellitus and DKA on liver enzymes and liver function tests.

Ultrasonography and biopsy may be useful in these cases to differentiate primary hepatic disease from secondary complications of diabetes mellitus such as hepatic lipidoses and cholangiohepatitis.

PANCREATIC DISEASE

Pancreatitis is a common concurrent disease with diabetes mellitus (also see Chapters 148 and 149). As such, it is not necessarily a complication of diabetes, but the two occur concurrently in about 40% of dogs and 50% of cats.

Cats and dogs with acute necrotizing pancreatitis usually present with vomiting, abdominal pain, and concurrent DKA. Physical examination findings include icterus, cranial abdominal pain, and abdominal effusion. Radiographs may reveal a "ground glass" appearance of the abdomen, and abdominal ultrasound usually shows enlargement and hypoechogenicity of the pancreas. Diagnostic peritoneal lavage is usually necessary to demonstrate inflammatory, nonseptic peritonitis; abdominal lipase is usually increased dramatically in affected cats and dogs.

If serum amylase and lipase are determined on presentation, they may be elevated in the absence of pancreatitis, secondary to severe dehydration, or renal insufficiency. Therefore demonstration of a high circulating concentration of pancreatic lipase immunoreactivity (PLI) may be a more reliable means of diagnosis.

OCULAR COMPLICATIONS OF DIABETES

The classical ocular complication of diabetes mellitus in dogs is the formation of diabetic cataracts. The incidence of cataracts in newly diagnosed diabetic dogs is about 40%; however, after a year of insulin therapy, the incidence of cataracts rises to about 80%. In contrast, cataracts are rare in cats with diabetes.

Polyol pathways in the eye rapidly convert glucose to sorbitol via aldose reductase and slowly to fructose via polyol dehydrogenase. In dogs this accumulation of sorbitol within the lens fibers may lead to imbibing water and eventual swelling and opacity of the lens. Older cats have lower aldose reductase activity. Since diabetes mellitus occurs in older cats more often than younger cats, this may explain the lack of cataracts in most diabetic cats compared with diabetic dogs.

Other complications of diabetes, more common in dogs than cats, include decreased corneal sensitivity, lens-induced uveitis, and keratoconjunctivitis sicca.

HYPOGLYCEMIA

Recent studies have suggested that as many as 25% of diabetic cats and approximately 10% of diabetic dogs experienced hypoglycemic episodes that required hospitalization. The dose of insulin prescribed for a newly diagnosed diabetic patient should be conservative (<2 U per cat BID and <0.5 U/kg for dogs). One large survey found that the majority of dogs presented for hypoglycemia were receiving insulin injections of greater than 1.5 U/kg. Overdosing, double-dosing, and persistent dosing in the face of anorexia or reduced food intake are common iatrogenic causes of hypoglycemia.

Common causes of noniatrogenic hypoglycemia in previously well-regulated diabetics frequently involve reversal of glucose toxicity in cats. Because cats are often type 2 diabetics, their insulin requirements can be extremely labile. With a change to a low-carbohydrate, high-protein diet, an increase in activity level, and a shift from body fat to body muscle, a cat's insulin requirement can change quickly and dramatically. To complicate matters further, the administration of insulin or oral hypoglycemic agents may reverse pancreatic islet cell resistance (glucose toxicity), resulting in a restoration of insulin secretory capability; this may result in hypoglycemia. For either dogs or cats, concurrent disease usually increases insulin requirements; thus, if the concurrent disease is controlled or resolved, insulin requirement may decline significantly.

To avoid hypoglycemia in diabetic patients, both written and verbal instructions should be given the owner. Common early warning signs of hypoglycemia such as nervousness and hyperexcitability in dogs and extreme lethargy in cats should be communicated to the owner.

The home remedy for a hypoglycemic crisis involves the application of glucose (i.e., Karo syrup) to the animal's mucous membranes; however, there is no evidence to suggest that this raises blood glucose concentrations significantly. If possible, the animal should be fed and transported to a veterinary facility for more aggressive intravenous glucose therapy. Prevention of hypoglycemia via client education is the best therapy.

DIABETIC KETOACIDOSIS

Frequently an underlying stressful event precipitates the shift from diabetes mellitus to DKA or nonketotic hyperosmolar diabetes mellitus. The precipitating event may be a urinary tract infection or other viral or bacterial infection or inflammatory disorder such as pancreatitis, pyelonephritis, cholangiohepatitis, IBD, eosinophilic granuloma complex, prostatitis, pyometra, upper respiratory infection, or pneumonia. Other concurrent diseases may include renal insufficiency or failure, hepatic lipodosis, neoplasia, or congestive heart failure. Recent drug therapy may also precipitate a crisis, especially administration of corticosteroids or progestagens.

Therefore further diagnostic testing of the diabetic patient that presents in a ketoacidotic crisis is essential. Abdominal radiography and/or ultrasonography, thoracic radiography, and echocardiography may be indicated. Additional testing for concurrent endocrine diseases such as hyperthyroidism in cats and hypothyroidism and hyperadrenocorticism in dogs may also be indicated; however, tests for hyperadrenocorticism should be postponed until some control of the diabetes mellitus is achieved because uncontrolled disease may affect the results of the tests.

DKA is the culmination of diabetes mellitus that results in unrestrained ketone body formation in the liver, metabolic acidosis, severe dehydration, shock, and possibly death. Hepatic lipid metabolism becomes deranged with insulin deficiency, and nonesterified fatty acids are converted to acetyl coenzyme A (acetyl CoA) rather than being incorporated into triglycerides. Acetyl CoA accumulates in the liver and is converted first to acetoacetyl

CoA and ultimately to acetoacetic acid, β -hydroxybutyrate (primary ketone body in dogs and cats), and acetone. As insulin deficiency culminates in DKA, accumulation of ketones and lactic acid in the blood and loss of electrolytes and water in the urine result in profound dehydration, hypovolemia, metabolic acidosis, and shock. Ketonuria and osmotic diuresis caused by glycosuria causes sodium and potassium loss in the urine, exacerbating hypovolemia and dehydration. Nausea, anorexia, and vomiting caused by stimulation of the chemoreceptor trigger zone via ketonemia and hyperglycemia contribute to the dehydration caused by osmotic diuresis. Dehydration leads to further accumulation of glucose and ketones in the blood. Stress hormones such as cortisol and epinephrine contribute to the hyperglycemia in a vicious cycle. Eventually severe dehydration may result in hyperviscosity, thromboembolism, severe metabolic acidosis, renal failure, and finally death.

Treatment of DKA includes the following steps in order of importance: (1) fluid therapy using 0.9% saline initially, followed by 2.5% or 5% dextrose as serum glucose falls; (2) insulin therapy (low-dose intramuscular or intravenous insulin); (3) electrolyte supplementation (i.e., potassium, phosphorus, magnesium); and (4) reversal of metabolic acidosis (Box 47-1).

Fluid therapy should consist of 0.9% NaCl supplemented with potassium when insulin therapy is initiated; however, hypernatremic patients may be rehydrated with lactated Ringer's solution to limit sodium load. Placement of a large central venous catheter is preferred for intravenous access because central venous pressure may be monitored, thereby providing the means to avoid overhydration. In addition, the need for repeated venipuncture necessary for frequent monitoring of glucose, electrolytes, and blood gases is eliminated. Rapid initiation of fluid therapy is the key for successful treatment of the DKA patient. Fluid rates vary, depending on degree of dehydration, maintenance requirements, continuing losses such as vomiting and diarrhea, and presence of diseases such as congestive heart failure and renal disease. Extreme caution should be exercised when considering initiating fluid therapy with a hypotonic solution because this increases the risk of cerebral edema. Fluids containing dextrose may be required to maintain blood glucose concentrations as insulin treatment for the DKA is continued.

In dogs insulin therapy should be initiated as soon as possible using either intravenous insulin or low-dose intramuscular methods (see Box 47-1). Intravenous continuous-rate infusion of regular insulin therapy is accomplished by placement of two catheters: a peripheral catheter for the insulin infusion and a central catheter for sampling blood and administering drugs and other fluids. A dosage of 2.2 U/kg for dogs or 1.1 U/kg for cats of regular (neutral, soluble) insulin is diluted in 250 ml of saline. Approximately 50 ml of fluid and insulin is allowed to run through the intravenous drip set and is discarded because insulin binds to the plastic tubing. The species of regular insulin (beef, pork, or human) does not affect response; however, the type of insulin given is very important. Regular insulin must be used; lente, isophane, and protamine zinc insulins should never be given intravenously. Using intravenous insulin administration, blood

Stepwise Treatment of Diabetic Ketoacidosis**Step One: Fluid Therapy**

- Place IV catheter, preferably central venous.

Administration rate:

- Estimate dehydration deficit (ml):

$$\text{Deficit (ml)} = \text{Dehydration (\%)} \times \text{body weight (kg)} \times 1000 \text{ ml}$$

- Estimate maintenance needs:

$$2 \text{ ml/kg/hr} \times \text{hours required to rehydrate (24 hours)}$$

- Estimate losses (vomiting, diarrhea)

Fluid dose = Dehydration deficit + maintenance needs + losses

Hourly fluid administration rate (ml/hr) = Fluid dose (ml) ÷ 24 hours

*Fluid Composition:***Blood Glucose**

(mg/dl)	Fluids	Rate	Route	Monitor	Frequency
>250	0.9% saline	Up to 90 ml/kg/hr to rehydrate	IV	PCV, TS, sodium, potassium, osmolality	Every 4 hr
200-250	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	PCV, TS, sodium, potassium, osmolality	Every 4 hr
150-200	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	Every 2 hr
100-150	0.45% saline plus 2.5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	Every 2 hr
<100	0.45% saline plus 5% dextrose	Up to 90 ml/kg/hr to rehydrate	IV	CVP, urine output	Every 2 hr

Step Two: Insulin

Intravenous insulin (regular only) is mixed in 250 ml of 0.9% saline; 50 ml is allowed to run through the administration set.

Blood Glucose (mg/dl)	Rate	Route	Dose (U/kg)	Monitor	Frequency
<i>Intravenous (regular only)</i>					
>250	10 ml/hr	IV	C: 1.1 D: 2.2	Blood glucose	Every 1-2 hr
200-250	7 ml/hr	IV	C: 1.1 D: 2.2	Blood glucose	Every 1-2 hr
150-200	5 ml/hr	IV	C: 1.1 D: 2.2	Blood glucose	Every 4 hr
100-150	5 ml/hr	IV	C: 1.1 D: 2.2	Blood glucose	Every 4 hr
<100	Stop intravenous insulin; begin subcutaneous insulin every 4 hours	SQ	0.1-0.4	Blood glucose	Every 2 hr
<i>Intramuscular (regular only)</i>					
>250 mg/dl	Initial dose	IM	0.2	Blood glucose	Hourly
	Every hour	IM	0.1	Blood glucose	Hourly
<250 mg/dl	Every 4-6 hr	IM	0.1	Blood glucose	Every 4-6 hr
	Every 6-8 hr	SQ	0.1-0.4	Blood glucose	Every 6-8 hr

Step Three: Electrolytes

Electrolyte Concentration	Amount Added to Fluid (mEq/L)	Maximum Fluid Administration Rate (ml/kg/hr)
<i>Potassium</i>		
3.6-5.0 mEq/L	20	26
2.6-3.5 mEq/L	40	12
2.1-2.5 mEq/L	60	9
<2.0 mEq/L	80	7
<i>Phosphorus</i>		
1-2 mg/dl	0.03 mmol/kg/hr	Monitor serum phosphorus every 6 hr
<1.0 mg/dl	0.1 mmol/kg/hr	Monitor serum phosphorus every 6 hr

glucose decreases to below 250 mg/dl by approximately 10 and 16 hours in dogs and cats, respectively. Once this has been achieved, the animal is maintained on subcutaneous regular insulin (0.1 to 0.4 U/kg subcutaneously every 4 to 6 hours) until it starts to eat and/or the ketosis has resolved. Often the transition from hospital to home maintenance therapy can be made by using a low dose (1 to 2 U) of regular insulin combined with the intermediate or long-acting maintenance insulin at the recommended dosages.

Potassium should be supplemented as soon as insulin therapy is initiated (see Box 47-1). Although serum potassium may be normal or elevated in DKA, the animal actually suffers from total body depletion of potassium. Correction of the metabolic acidosis tends to drive potassium intracellularly in exchange for hydrogen ions. Insulin facilitates this exchange, and the net effect is a dramatic decrease in serum potassium, which must be attenuated with appropriate potassium supplementation in fluids. Refractory hypokalemia may be complicated by hypomagnesemia. Supplementation of magnesium along with potassium may be indicated in cats or dogs with hypokalemia that is unresponsive to potassium chloride supplementation.

Serum and tissue phosphorus may also be depleted during a ketoacidotic crisis, and some of the potassium supplementation should consist of potassium phosphate (one third of the potassium dose as potassium phosphate), particularly in small dogs and cats that are most susceptible to hemolysis caused by hypophosphatemia. Caution should be used since oversupplementation of phosphorus can result in metastatic calcification and hypocalcemia.

Bicarbonate therapy may be necessary in some patients with a blood pH less than 7.1 or if serum HCO_3^- is less than 12 mmol/L. Caution is recommended as metabolic alkalosis may be difficult to reverse.

NONKETOTIC HYPEROSMOLAR DIABETES

Nonketotic hyperosmolar diabetes is defined by extreme hyperglycemia (>600 mg/dL), hyperosmolality (>350 mOsm/L), severe dehydration, and central nervous system (CNS) depression without ketone formation and

with no or only mild metabolic acidosis. Affected animals commonly have underlying renal or cardiovascular disease and are more likely to be noninsulin dependent.

Although this specific syndrome, as defined in humans, is uncommonly encountered in veterinary medicine, it is not uncommon to have ketotic or nonketotic diabetic cats with significant hyperosmolality and CNS alterations. Treatment consists of slow rehydration with isotonic or hypotonic fluids and postponement of insulin therapy for 24 hours.

Atypical and Subclinical Hyperadrenocorticism

J. CATHARINE R. SCOTT-MONCRIEFF, *West Lafayette, Indiana*

Classical hyperadrenocorticism is a syndrome caused by excess secretion of cortisol from the adrenal gland(s). Approximately 80% to 85% of cases of spontaneous hyperadrenocorticism in both dogs and cats are caused by pituitary-dependent hyperadrenocorticism, with the remainder the result of a functional adrenocortical tumor. Although cortisol is the major product of the adrenal gland, which is typically oversecreted in hyperadrenocorticism, excessive secretion of other adrenocortical hormones (i.e., sex hormones and mineralocorticoids) has also been documented. In some dogs with signs of hyperadrenocorticism, cortisol excess cannot be demonstrated, but increased concentrations of adrenal sex steroids are found. In these situations measurement of sex hormones may provide useful additional diagnostic information to support a diagnosis of hyperadrenocorticism.

ADRENAL STEROID HORMONE PRODUCTION IN THE ADRENAL CORTEX

Adrenal steroids are derived from cholesterol. Four cytochrome P-450 enzymes present in the adrenal cortex (side chain cleavage enzyme, 17 α -hydroxylase, 21 β -hydroxylase, and 11 β -hydroxylase), and one noncytochrome enzyme (3 β -dehydrogenase) catalyze formation of the different adrenal steroids (Fig. 48-1).

The adrenal cortex is composed of three zones: the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa is deficient in 17 α -hydroxylase activity; thus it is incapable of synthesizing cortisol or androgens. The zona glomerulosa does contain aldosterone synthase, which catalyzes the synthesis of aldosterone from corticosterone. The major secretory products of the zona fasciculata and zona reticularis in normal animals are cortisol and the adrenal androgens dehydroepiandrosterone and androstenedione. The zona fasciculata and zona reticularis cannot synthesize aldosterone. Although progesterone is synthesized in the adrenal gland as a precursor to androgens in healthy dogs, very little progesterone is normally secreted into the circulation. Similarly in normal animals only very small amounts of testosterone and estrogen are synthesized by the adrenal cortex; however, adrenal androgens serve as substrates for synthesis of testosterone and estrogen in peripheral tissues.

Cortisol production from the adrenal gland is regulated by the hypothalamic-pituitary-adrenal axis. Aldosterone production is regulated by the renin-angiotensin system, the plasma potassium concentration, and to a lesser

extent the hypothalamic-pituitary-adrenal axis. Regulation of secretion of other adrenal steroid hormones is poorly understood but likely involves both adrenocorticotrophic hormone (ACTH) and other non-ACTH factors.

CLINICAL SIGNS OF HYPERADRENOCORTICISM

Clinical signs of hyperadrenocorticism include polydipsia, polyuria, polyphagia, abdominal enlargement, hepatomegaly, cutaneous changes (e.g., alopecia, cutaneous atrophy, calcinosis cutis, hyperpigmentation), muscle weakness, decreased exercise tolerance, excessive panting, truncal obesity, lethargy, weight gain, immunosuppression, insulin resistance, and decreased sexual function. Although excessive circulating concentrations of cortisol are the primary cause of clinical signs in dogs with spontaneous hyperadrenocorticism, increased circulating concentrations of other adrenal steroid hormones such as progesterone or 17-hydroxyprogesterone may also cause clinical signs that are indistinguishable from those caused by glucocorticoid excess. This is hypothesized to be caused by the marked intrinsic glucocorticoid activity of progestagens. In addition, progestins may increase availability of cortisol by displacing it from its binding proteins. In rare cases of hyperadrenocorticism, increased concentrations of adrenal androgens, estrogens, and mineralocorticoids may cause virilization, feminization, or hypertension, respectively.

DIAGNOSIS OF HYPERADRENOCORTICISM

Diagnosis of hyperadrenocorticism is made by consideration of historical findings, physical examination, review of a laboratory minimum database (i.e., complete blood count, serum biochemical profile, urinalysis), and pituitary-adrenal endocrine function testing. Commonly performed screening endocrine tests include the ACTH stimulation test, the low-dose dexamethasone suppression test, and the urine cortisol:creatinine ratio.

ACTH Stimulation Test

This test relies on the assumption that hyperplastic or neoplastic adrenals have abnormally large reserves of cortisol and therefore hyperrespond to ACTH administration with maximal stimulation. The ACTH stimulation test is abnormal in 85% to 90% of dogs with

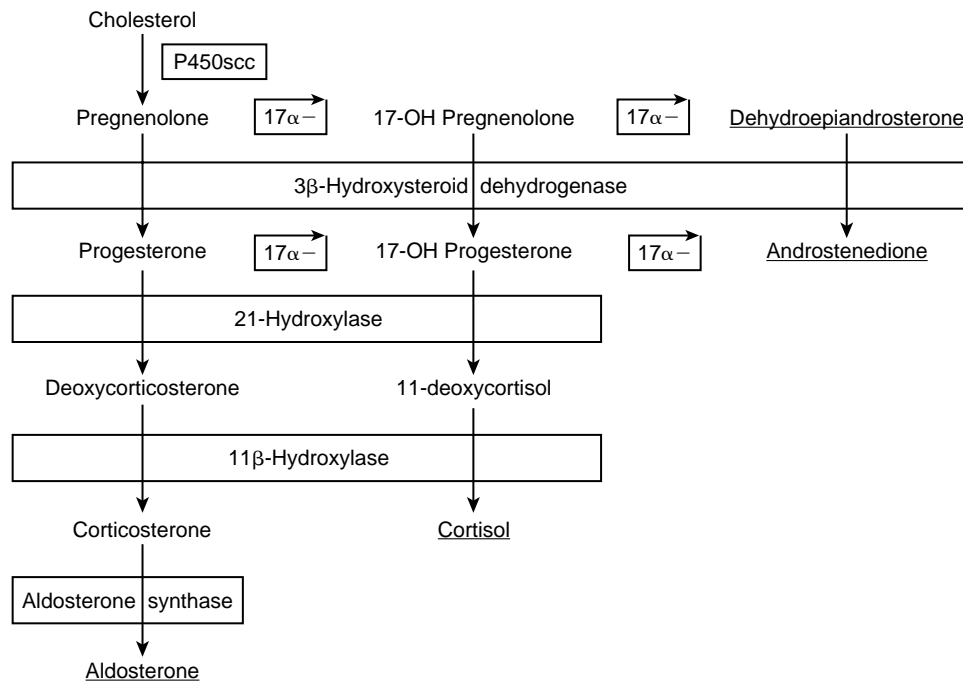

Fig. 48-1 Pathway for adrenal steroid hormone synthesis within the adrenal gland.

pituitary-dependent hyperadrenocorticism and in 50% of dogs with functional adrenocortical tumors. Advantages of the ACTH stimulation test are that it allows differentiation of iatrogenic from spontaneous hyperadrenocorticism and is less affected by stress and concurrent disease than the low-dose dexamethasone suppression test. However, the ACTH stimulation test cannot distinguish between dogs with adrenocortical tumors or pituitary-dependent hyperadrenocorticism. Because of the low sensitivity of this test, a diagnosis of hyperadrenocorticism should not be excluded based on a normal ACTH stimulation.

Low-Dose Dexamethasone Suppression Test

The low-dose dexamethasone suppression test is a better screening test for hyperadrenocorticism since it is more sensitive (95%) than the ACTH stimulation test. However, it does not allow detection of iatrogenic hyperadrenocorticism. Administration of an adequate dose of exogenous glucocorticoids suppresses the secretion of ACTH from the normal pituitary and therefore the production of cortisol from the normal adrenal gland. This suppression persists in the normal dog for 24 to 48 hours. Since dexamethasone is not detected by the assay for cortisol, a decrease in cortisol secretion can be measured after dexamethasone administration. Adrenal tumors function independently of ACTH control, whereas a hyperplastic or neoplastic pituitary gland is relatively resistant to negative-feedback inhibition from circulating steroids; therefore cortisol suppression fails to occur in dogs with either type of hyperadrenocorticism.

Urinary Cortisol:Creatinine Ratio

The urine cortisol:creatinine ratio is an estimate of 24-hour cortisol production by the adrenal gland. The measurement is made on a voided morning urine sample collected at home; thus it is a very convenient initial screening test. The urine cortisol:creatinine ratio is an extremely sensitive test for diagnosis of hyperadrenocorticism but has *low specificity*. A urine cortisol:creatinine ratio within the reference range is helpful in ruling out hyperadrenocorticism as a differential diagnosis; however, many nonadrenal diseases also increase the urine cortisol:creatinine ratio; thus further testing is necessary for confirmation.

Differentiation of Pituitary-Dependent Hyperadrenocorticism From Adrenal Tumors

Clinical and routine laboratory findings are not useful in distinguishing pituitary-dependent hyperadrenocorticism from functional adrenal tumors. The ACTH stimulation test and urine cortisol:creatinine ratio do not differentiate adrenal tumors from pituitary-dependent hyperadrenocorticism.

The low- and high-dose dexamethasone suppression tests and measurement of the endogenous ACTH concentration are the most useful endocrine tests for distinguishing adrenocortical tumor from pituitary-dependent hyperadrenocorticism. Additional tests that may be necessary to differentiate dogs with pituitary-dependent hyperadrenocorticism from those with adrenocortical tumors include abdominal radiography, abdominal ultrasound, and computed tomography (abdomen and brain).

Problems in Diagnosis: Atypical Hyperadrenocorticism

Although in most dogs with hyperadrenocorticism the diagnosis is straightforward, there are some dogs with clinical signs suggestive of hyperadrenocorticism that have normal ACTH stimulation and low-dose dexamethasone suppression test results. In many of these dogs other causes for the clinical signs have been ruled out, and in some repeated cortisol testing over a period of several months confirms diagnosis of hyperadrenocorticism. Dogs with overt clinical signs of hyperadrenocorticism, lack of evidence for cortisol excess by routine endocrine testing, and positive response to treatment for hyperadrenocorticism have been described as having atypical hyperadrenocorticism. Measurement of serum concentrations of other adrenal steroid hormones may assist in diagnosis of such cases.

ADRENAL STEROID HORMONE SECRETION PATTERNS IN DOGS AND CATS

Normal Dogs

Concentrations of many of the adrenal steroid hormones vary, depending on the dog's sex and neuter status; therefore reference ranges must be established for each sexual category. Most hormones increase after administration of ACTH, and evaluation of both pre-ACTH and post-ACTH samples is recommended.

Dogs With Classical Hyperadrenocorticism

Most dogs with classic hyperadrenocorticism (confirmed by use of ACTH stimulation or low-dose dexamethasone suppression tests) also have elevations of other steroid adrenal hormones both before and after stimulation with ACTH. Hormones that are commonly increased include dehydroepiandrosterone, androstenedione, progesterone, and 17-hydroxyprogesterone. Although testosterone and estradiol concentrations are evaluated as part of some adrenal steroid hormone panels, they are less commonly abnormal. Profiles observed in dogs with hyperadrenocorticism vary from dog to dog, but most dogs with classical hyperadrenocorticism have at least one steroid hormone (in addition to cortisol) that is increased. Typically two-to-three hormone concentrations are abnormal; however, it is unusual for all hormones in the profile to be increased.

Adrenal steroid hormone concentrations may be increased in dogs with either pituitary-dependent hyperadrenocorticism or adrenocortical tumor. Although the highest concentrations are typically found in dogs with adrenocortical carcinomas, there is extensive overlap between dogs with pituitary-dependent hyperadrenocorticism and adrenocortical tumor.

Concentration of 17-hydroxyprogesterone has been evaluated most extensively in dogs with hyperadrenocorticism. The percentage of dogs with hyperadrenocorticism that have an increase in 17-hydroxyprogesterone after stimulation with ACTH ranges from 55% to 85% (Benitah et al., 2005; Hill et al., 2005). Thus sensitivity of

17-hydroxyprogesterone for diagnosis of classical hyperadrenocorticism is lower than that reported for measurement of cortisol after ACTH stimulation.

Dogs With Nonadrenal Illness

Some dogs with nonadrenal illness also have increases in 17-hydroxyprogesterone secretion. In a group of dogs with nonadrenal neoplasia that did not have clinical signs of hyperadrenocorticism, 11 of 35 (31%) had high post-ACTH 17-hydroxyprogesterone concentrations, whereas only 3 of 35 (9%) had high cortisol concentrations after ACTH stimulation (Behrend et al., 2005). This suggests that the specificity of 17-hydroxyprogesterone for diagnosis of hyperadrenocorticism is lower than that of serum cortisol. Similar results were reported for measurement of corticosterone concentration.

Specificity of other adrenal steroid hormone measurement for diagnosis of hyperadrenocorticism has not been reported. However, four of six dogs with noncortisol secreting adrenal tumors (five of which were pheochromocytomas) had one or more abnormalities on an adrenal steroid hormone profile in one study (Hill et al., 2005).

Dogs With Atypical Hyperadrenocorticism

In dogs with atypical hyperadrenocorticism, serum cortisol concentrations measured during routine endocrine function testing (with ACTH stimulation, low-dose dexamethasone suppression, or urine cortisol:creatinine ratio) are within or below the reference range, whereas other adrenal steroid hormone concentrations may be increased. The reason for lack of hypercortisolemia in dogs with atypical hyperadrenocorticism is poorly understood. In those with adrenocortical tumor, mutations within neoplastic adrenal tissue may lead to a blockade of cortisol synthesis (see Noncortisol-Secreting Adrenal Tumors later in the chapter), but atypical hyperadrenocorticism has also been well documented in dogs with pituitary-dependent hyperadrenocorticism. It is likely that these dogs have increased adrenal steroid hormone concentrations as a result of adrenal gland hyperplasia and increased secretion of all adrenal gland products. It is possible that 24-hour production of cortisol is abnormal in these dogs, even though random circulating cortisol concentration is within reference range limits. Further studies are necessary to investigate the cause of atypical hyperadrenocorticism, especially in dogs with pituitary-dependent hyperadrenocorticism.

In dogs with clinical signs supportive of hyperadrenocorticism that have normal or borderline results on routine cortisol testing, marked increases in two or three adrenal steroid hormone concentrations are very supportive of a diagnosis of atypical hyperadrenocorticism. An example of an adrenal steroid hormone panel in a dog with clinical signs of hyperadrenocorticism in which a diagnosis of atypical pituitary-dependent hyperadrenocorticism was made is shown in Table 48-1.

Table 48-1

Adrenal Steroid Hormone Profile in a 13-year-old Male Castrated Terrier With Pituitary-Dependent Atypical Hyperadrenocorticism*

Adrenal Hormone	Basal Concentration	Reference Range	Post ACTH	Reference Range
Cortisol (mcg/dl)	1.8	1-6	18.3	7-17
Androstenedione (ng/ml)	3.7	0.1-3.6	87.6	2.4-29
Estradiol (pg/ml)	95.7	23-85	93.4	23-89
Progesterone (ng/ml)	0.06	0.01-0.17	3.66	0.22-1.45
17-hydroxyprogesterone (ng/ml)	0.17	0.01-0.24	6.59	0.02-0.42

ACTH, Adrenocorticotrophic hormone.

*Low-dose dexamethasone suppression test was normal. All clinical signs resolved after treatment with mitotane.

Dogs and Cats With Non-cortisol-Secreting Adrenal Tumors

In some dogs and cats with functional adrenocortical tumors, adrenal steroid hormones other than cortisol are the major secretory product of the tumor, and serum cortisol concentrations are low. Increased production of adrenal steroids other than cortisol may be caused by deficiencies of one or more enzymes involved in normal steroidogenic pathways, possibly the result of mutations in neoplastic adrenal tissue. Deficiency of these enzymes causes accumulation of precursor steroids proximal to the blocked step, with shunting of precursors into other metabolic pathways (see Fig. 48-1). Increases in enzyme activity may also play a role in steroid hypersecretion. Circulating cortisol concentrations in these dogs are hypothesized to be low because of suppression of the hypothalamic-pituitary axis by high circulating concentrations of progestins or other adrenal sex hormones.

All reported cases of non-cortisol-secreting adrenal tumors in dogs and cats have been carcinomas. This is similar to the situation in humans in which adrenal carcinomas are usually inefficient in conversion of cholesterol to cortisol and production of cortisol precursors is disproportionately high. In contrast, adrenal adenomas generally exhibit very efficient steroidogenesis, and production of precursors is low or normal in relation to cortisol production.

In dogs and cats with non-cortisol-secreting adrenocortical carcinomas, clinical signs are generally consistent with those of hyperadrenocorticism, and adrenal tumors are identified by imaging studies. However, endocrine function tests do not demonstrate hypercortisolemia, and results of ACTH stimulation testing typically show low cortisol concentrations that do not increase normally after ACTH administration. Hormones that have been reported to be increased in different combinations are 17-hydroxyprogesterone, progesterone, estradiol, testosterone, and androstenedione. Increased concentrations of corticosterone and aldosterone have also been reported in dogs and cats with non-cortisol-secreting adrenocortical carcinomas. An example of an adrenal steroid hormone panel in a dog with clinical signs of hyperadrenocorticism in which a non-cortisol-secreting carcinoma was diagnosed is shown in Table 48-2. The clinical syndrome of non-cortisol-secreting adrenocortical tumors in dogs and cats appears to be a distinctly different entity from dogs with classical hyperadrenocorticism that secrete sex hormones in conjunction with normal-to-increased cortisol concentrations.

Dogs With Alopecia X

Alopecia X is a form of canine adult-onset alopecia that may be caused by mild hyperadrenocorticism. The problem affects Nordic breeds (Alaskan malamute, chow-chow,

Table 48-2

Adrenal Steroid Hormone Profile in a 9-year-old Male Castrated Poodle With Adrenocortical Carcinoma*

Adrenal Hormone	Basal Concentration	Reference Range	Post ACTH	Reference Range

ACTH, Adrenocorticotrophic hormone.

*All hormone concentrations normalized following resection of the tumor.

keeshond, Pomeranian, Samoyed, Siberian husky) and also the miniature poodle. Affected dogs have no other clinical signs of systemic illness; some studies have demonstrated borderline ACTH stimulation and low-dose dexamethasone suppression test results and mild increases in the cortisol:creatinine ratios in affected dogs. A mild form of hyperadrenocorticism is suspected in at least some affected dogs.

Many dogs with alopecia X have increased serum sex hormone concentrations, both basally and following ACTH stimulation testing. The most frequent abnormalities detected include increased concentrations of progesterone, androstenedione, and 17-hydroxyprogesterone, although not all dogs have values outside the reference range.

CLINICAL INDICATIONS FOR ADRENAL STEROID HORMONE PANEL

At this time it is not recommended that adrenal steroid hormone measurement be used for routine diagnosis of hyperadrenocorticism. However, measurement of a panel of adrenal steroid hormones before and after ACTH stimulation should be considered in dogs that have clinical signs and clinical laboratory evidence for hyperadrenocorticism, no evidence of another cause for their clinical signs, and normal or borderline cortisol testing on routine endocrine testing. Adrenal steroid hormone measurement should also be considered in dogs and cats with clinical signs of hyperadrenocorticism and suppressed cortisol concentrations after ACTH stimulation if treatment with exogenous steroids or mitotane is ruled out; this is particularly true if an adrenal mass is visualized with ultrasound or computed tomography. Measurement of an adrenal steroid hormone profile may also be useful in dogs with suspected alopecia X. Because of the paucity of information about the specificity of these measurements, every effort should be made to rule out other causes for the observed clinical signs before running an adrenal steroid hormone panel.

A number of laboratories offer individual adrenal steroid hormone assays. The most extensive adrenal steroid hormone profile is offered by the Clinical Endocrinology Service at the University of Tennessee. Their profile includes androstenedione, estradiol, progesterone, 17-hydroxyprogesterone, and aldosterone. The protocol for running the test is identical to that for a standard ACTH stimulation test, but the profile requires a larger sample (2 ml) of serum. In a dog with clinical signs of hyperadrenocorticism, marked increases (1.5 to 2 times greater than the high end of the reference range) of at least two and preferably three adrenal steroid hormone concentrations is consistent with a diagnosis of atypical hyperadrenocorticism.

TREATMENT OF ATYPICAL HYPERADRENOCORTICISM

Dogs with pituitary-dependent atypical hyperadrenocorticism respond well to routine therapy for hyperadrenocorticism (see Chapter 49). Good clinical responses have been reported with both mitotane and trilostane. No

advantage of trilostane treatment over mitotane has been documented.

Although most dogs with atypical pituitary-dependent hyperadrenocorticism have borderline or normal cortisol responses to ACTH stimulation, routine ACTH stimulation tests with measurement of cortisol alone are adequate for monitoring therapy. The reason for this is that the goal of treatment is suppression of cortisol concentration below the reference range for post-ACTH cortisol (2 to 6 mcg/dl).

Monitoring adrenal steroid hormone profiles during treatment is not currently recommended because of expense and limited usefulness. For example, in dogs with atypical hyperadrenocorticism successfully treated with mitotane, 17-hydroxyprogesterone concentrations decrease; in those treated with trilostane, 17-hydroxyprogesterone concentrations increase despite a positive clinical response to therapy. Since trilostane inhibits the 3 β -dehydrogenase enzyme, 17-hydroxyprogesterone would be predicted to decrease, not increase. It is possible that trilostane acts at additional steps in the synthetic cascade or that there is cross-reactivity of the assay for 17-hydroxyprogesterone with precursors such as pregnenolone and hydroxypregnenolone.

Although melatonin has been demonstrated to decrease sex hormone concentrations in normal dogs, there is no evidence to suggest that this is an effective therapy in dogs with atypical hyperadrenocorticism. Mitotane, trilostane, and melatonin have all been reported to be effective in the treatment of some dogs with alopecia X; however, dogs that responded to melatonin did not have decreases in adrenal steroid hormone concentrations during treatment.

In dogs with adrenocortical tumors, whether typical or atypical, the treatment of choice is usually surgical resection. Although some cortisol-secreting adrenal tumors do respond well to medical therapy with mitotane or trilostane, noncortisol-secreting adrenocortical tumors tend to respond poorly to medical management with either mitotane or trilostane.

CHAPTER 49

Canine Hyperadrenocorticism

IAN RAMSEY, *Glasgow, United Kingdom*
RETO NEIGER, *Giessen, Germany*

Hyperadrenocorticism, or Cushing's syndrome, results from a chronic excess of glucocorticoids and is one of the most common canine endocrinopathies. This chapter summarizes the current knowledge of the treatment of this syndrome. Attention is focused on recent developments such as the use of trilostane. For a detailed description of the more well-known aspects of this disease, readers should consult one of the standard textbooks.

Hyperadrenocorticism has two spontaneous forms and may also be produced iatrogenically by the administration of steroids. The most common cause of hyperadrenocorticism is the overproduction of adrenocorticotrophic hormone (ACTH) by a small, benign pituitary microadenoma (pituitary-dependent hyperadrenocorticism). A less common cause of hyperadrenocorticism, accounting for about 15% of cases, is the overproduction of cortisol by an adrenal tumor (adrenal-dependent hyperadrenocorticism).

It is useful, but not always essential, to distinguish between pituitary-dependent-hyperadrenocorticism and adrenal-dependent hyperadrenocorticism. Differentiating between the two causes of hyperadrenocorticism helps improve the treatment that can be offered and provides information on the likely prognosis and progression of the condition. Interested readers should consult Chapter 38 and other texts for a full discussion of the various methods of achieving this distinction (e.g., low-dose dexamethasone suppression test, endogenous ACTH assay, and abdominal ultrasonography).

TREATMENT OF PITUITARY-DEPENDENT HYPERADRENOCORTICISM

In general, all dogs with pituitary-dependent hyperadrenocorticism should be treated. However, cases

identified fortuitously during routine health checks may not require immediate treatment. The risks of not treating hyperadrenocorticism, especially when more advanced, include the development of pulmonary thromboembolism, diabetes mellitus, and calcium oxalate urolithiasis.

Treatment of pituitary-dependent hyperadrenocorticism may be associated with the unmasking of steroid-responsive diseases, including arthritis and atopic dermatitis. The sudden reduction in cortisol concentrations may result in rapid growth of a pituitary tumor, leading to neurologic signs such as ataxia, depression, apparent blindness, inappetence, aimless walking, seizures, and alteration in normal behavior patterns. Treatment may also be associated with a unilateral facial nerve paralysis; it is often unclear if this is a result of the disease or the treatment, but it is seen with both trilostane and mitotane therapy.

Owners of dogs with pituitary-dependent hyperadrenocorticism often ask for the "best" treatment. The answer to this question is now more complicated than it has ever been, and there are at least three effective treatments. No one regimen is perfect for all cases. Local laws and personal experience are important factors in determining the advice that is offered.

Surgical Options

Transsphenoidal hypophysectomy has been described for the treatment of pituitary tumors in dogs with pituitary-dependent hyperadrenocorticism. Only specialists working in suitable facilities should perform such surgery. The success rate in experienced hands is acceptable, but serious complications may occur. Currently only one institution in Europe performs this procedure on a regular basis.

Medical Options

Mitotane

This drug is the mainstay of medical management of hyperadrenocorticism in many countries and is reviewed in detail elsewhere (Kintzer and Peterson, 1991). It is a cytotoxic agent that principally causes necrosis of the zona fasciculata and zona reticularis of the adrenal glands. It is slightly more efficacious than trilostane (see next section) but is reported to have a higher incidence of side effects (Kintzer and Peterson, 1991). Because it can be absorbed through the skin and is cytotoxic to humans, it should be handled carefully with gloves. Splitting tablets should be avoided when possible.

Mitotane is given initially as an induction course (50 mg/kg orally) administered once daily or divided twice daily, as required. Since it is a drug that has a narrow therapeutic index, stabilization in a hospital should be considered in some cases (e.g., dogs with concurrent diabetes) during the induction phase. The drug should be administered either in or immediately following a meal since this enhances its absorption. The induction course is monitored by carefully measuring the dog's water intake and observing its feeding behavior. Concomitant prednisolone administration is generally not recommended. Mitotane can also be used at higher doses in a protocol designed to permanently destroy the adrenal gland. This protocol is no longer in widespread use, and readers are advised to consult relevant texts for further details.

Treatment is stopped when the water consumption or the appetite starts to decrease. Once these end points are reached, if the animal is unusually listless, begins vomiting, or has diarrhea or 7 days of treatment have elapsed, an ACTH stimulation test is performed. A response indicative of mild adrenal cortex suppression indicates satisfactory control. For most laboratories this means a post-ACTH cortisol less than 120 nmol/L (<4.3 mcg/dl).

Most induction courses last 5 to 10 days. Almost all dogs with pituitary-dependent hyperadrenocorticism respond by day 14. Maintenance therapy (25 to 50 mg/kg orally every 7 days) is then given and checked by ACTH stimulation tests, initially every month and then every 3 months.

Many dogs show relapses at some stage and require adjustments to the dose of mitotane. Responses to ACTH stimulation tests that suggest a failure of adrenal suppression (post-ACTH cortisol greater than 250 nmol/L (>9 mcg/dl)) should be treated with a 3-day reinduction course and the effects of this monitored with further ACTH stimulation tests.

Dogs that are treated with mitotane, particularly those that have been treated for several months, may develop acute signs of hypoadrenocorticism (e.g., severe depression, anorexia, vomiting, and diarrhea). Intravenous fluids, glucocorticoids, and rest are usually effective.

Occasionally there may be evidence of hyperkalemia and hyponatremia. If these occur, an ACTH stimulation test should be performed; post-ACTH cortisol would be expected to be less than 20 nmol/L or (<0.7 mcg/dl). Mineralocorticoids should be given if hyperkalemia has been documented (see Chapters 50 and 51). Pancreatitis and hemorrhagic gastroenteritis are potential complications of the acute iatrogenic hypoadrenocorticism. Oral

prednisolone (0.2 to 0.4 mg/kg orally every 24 hours) is given once the vomiting has subsided. Some dogs require this for life, but others may revert to their original state of hyperadrenocorticism.

Routine monitoring with ACTH stimulation tests is recommended; the frequency of monitoring largely depends on the clinical progression of the case. Some dogs receiving long-term prednisolone as a result of mitotane-induced hyperadrenocorticism only require ACTH stimulation tests annually.

Some animals become intolerant of mitotane and show signs of gastrointestinal upset without a reduction in post-ACTH cortisol concentrations. These dogs should be treated by other means.

Trilostane

Trilostane is a synthetic steroid that competitively inhibits steroid synthesis by blocking 3 β -hydroxysteroid dehydrogenase. The adrenal glands and in particular the synthesis of glucocorticoids are more susceptible to its action than other steroid-producing tissues. The reasons for this are not known. Trilostane is now licensed in most European countries for the treatment of canine hyperadrenocorticism, and it can be obtained in the United States from the European manufacturer (Dechra Ltd, UK) by completing a letter with all the necessary information (form sent to the Division of Compliance HFA-230, Centre of Veterinary FDA, Metro Park North, 7500 Standish Place, Rockville MD 20855).

Trilostane has been found to be well tolerated by almost all dogs with pituitary-dependent hyperadrenocorticism in several published trials (totaling more than 120 dogs) and also two unpublished large multicenter studies performed for licensing purposes. Very few dogs develop signs of hypoadrenocorticism when treated with trilostane, although mild asymptomatic hyperkalemia is quite common. When hypoadrenocorticism does occur, dogs usually rapidly recover with appropriate therapy. A very few dogs have died despite withdrawal of trilostane and administration of appropriate therapy. A few sudden deaths without signs of hypoadrenocorticism while on trilostane therapy have also occurred; the role of trilostane in these cases has not been determined. The low prevalence of side effects compares favorably to those reported with mitotane.

Trilostane is safer for owners to handle when compared to mitotane. However, pregnant women are advised to wear gloves when handling the drug since it has been shown to cause abortion in monkeys given large doses.

Although few pharmacokinetic studies have been performed, trilostane is known to be short acting. The recommended starting dose is 2 to 5 mg/kg orally once daily, using the lower dosage range in small dogs. Trilostane is absorbed better if given with food. It is effective in resolving the signs of pituitary-dependent hyperadrenocorticism in about 75% of cases (Neiger and colleagues, 2002; Ruckstuhl, Nett, and Reusch, 2002). Polyuria, polydipsia, and polyphagia should dissipate within 4 weeks after starting trilostane. If this has not happened, the dose should be increased. Skin changes should resolve within 4 months of starting treatment. All these improvements should be maintained as long as the dogs remain on adequate doses of trilostane.

The efficacy of the drug and the required dosages are assessed using ACTH stimulation tests carried out 7 to 14 days, 30 days, and 90 days after starting therapy. ACTH stimulation tests should be started 4 hours after dosing; however, it is probably acceptable to start as early as 2 hours after dosing and as late as 5 hours (such that the last sample is then taken at 6 hours). There are significant differences between the cortisol responses to ACTH if stimulation tests are performed at other times (Bell and colleagues, 2006). Many dogs require a change in dose (increase or decrease), and much higher doses may be required in some cases. Doses up to 40 to 50 mg/kg (divided twice daily) have been given with no unwanted side effects (Braddock and associates, 2003).

Post-ACTH cortisol concentrations should be between 40 nmol/L (1.5 mcg/dl) and 150 nmol/L (5.6 mcg/dl). If the post-ACTH cortisol concentration is lower, trilostane is stopped for 5 to 7 days and reintroduced at a lower dose. If the post-ACTH cortisol concentration is higher, the dose of trilostane may need to be increased, depending on the resolution of clinical signs. However, if the post-ACTH cortisol concentration is between these two values and the patient appears not to be clinically well controlled, the trilostane may need to be given twice daily. If an ACTH stimulation test is performed inadvertently at times other than 2 to 6 hours after dosing with trilostane, the post-ACTH cortisol concentration should be greater than 20 nmol/L (0.7 mcg/dl) and less than 250 nmol/L (9 mcg/dl).

Once the clinical condition of the animal and the dosage rate have been stabilized, the dog should be examined, and an ACTH stimulation test performed every 3 months. Serum biochemistry (especially potassium measurement) can be performed periodically to check for hyperkalemia, but with increasing clinical experience this becomes less important. Many dogs show relapses at some stage and require adjustments to the dosage of trilostane.

Care should be exercised when using trilostane with aldosterone antagonists (such as spironolactone), and the effects of angiotensin-converting enzyme inhibitors may be potentiated. The drug should be used with greater caution in animals with preexisting renal or cardiac disease. No specific data on drug interactions exist, and these comments are purely precautionary. No unwanted drug interactions have been seen in dogs receiving trilostane and various nonsteroidal antiinflammatory drugs, antibiotics, insulin preparations, and levothyroxine.

Minor side effects are sometimes seen, such as mild lethargy, decreased appetite, and slight electrolyte abnormalities. These may occur from 2 to 4 days after the start of the therapy and are often transient and respond to dose reduction. If more serious signs of vomiting, diarrhea, or lethargy develop, trilostane should be stopped, and prednisolone given for 1 or 2 days. In some cases dogs may require very much lower doses for the remainder of their lives. This has been linked to acute adrenal necrosis, the cause of which remains unknown.

Long-term adverse effects have not been documented, but it has been suggested that adrenal glands increase in size in response to therapy, probably as a result of chronic overstimulation with endogenous ACTH. There have

been no documented instances of adrenal tumors developing in trilostane treated dogs.

The survival of dogs with pituitary-dependent hyperadrenocorticism treated with trilostane or mitotane have recently compared (Barker and colleagues, 2005). There was no significant difference between the 123 trilostane-treated dogs, surviving a median of 662 days (range 8 to 1971 days), and the 25 mitotane-treated dogs, surviving a median of 708 days (range 33 to 1339 days). A comparison of twice-daily trilostane with mitotane-induced adrenocorticolysis also did not demonstrate a significant difference.

It is important to note that many aspects of trilostane use in canine hyperadrenocorticism are still under investigation; therefore the above recommendations may change. Veterinarians who are unfamiliar with the use of the drug should consult the manufacturer or recognized specialist for up-to-date information.

Other Medical Treatments

Ketoconazole at high serum concentrations inhibits steroid synthesis and therefore exerts effects similar to those of trilostane. In those countries where trilostane is unavailable, ketoconazole is indicated for the treatment of pituitary-dependent hyperadrenocorticism, particularly in dogs that cannot tolerate mitotane. Ketoconazole is hepatotoxic at high doses. The initial dose is 5 mg/kg orally every 12 hours for 7 days. If there are no problems, the dose may be increased by 5 mg/kg orally every 12 hours until control is achieved or a maximum dose of 30 mg/kg is being given. An ACTH stimulation test is performed 1 week later. The same target range as for trilostane and mitotane is used, with a goal of post-ACTH cortisol concentrations between 20 and 120 nmol/L (0.7 to 4.3 mcg/dl).

In the United States and some other countries, *selegiline* (L-Deprenyl) is licensed for the treatment of pituitary-dependent hyperadrenocorticism. It is thought to increase dopamine concentrations in the brain and thereby decrease ACTH production. The dose is 1 mg/kg orally every 24 hours for 60 days, increasing to 2 mg/kg after this time if there is no response. If there is no response after a further month, alternative therapy should be considered. The current evidence indicates that there is minimal endocrinologic but some clinical improvement with selegiline therapy (Reusch, Steffen, and Hoerauf, 1999).

Various other drugs have been suggested for the treatment of hyperadrenocorticism, including phosphatidylserine, cyproheptadine, metapyrone, and aminoglutethimide. Some of these drugs have been found to be ineffectual; others have not been investigated. None are currently regarded as useful treatments for canine hyperadrenocorticism.

TREATMENT OF DOGS WITH PITUITARY-DEPENDENT HYPERADRENOCORTICISM AND NEUROLOGIC SIGNS

Neurologic signs may develop during any stage of treatment; these usually indicate an expanding pituitary tumor. Magnetic resonance imaging and to a lesser extent computed tomography can diagnose such a tumor in

dogs that have pituitary-dependent hyperadrenocorticism and neurologic signs. The presence of a large intracranial tumor should not be regarded as a poor prognostic sign per se, although the chance of intracranial hemorrhage (pituitary apoplexy) or the sudden expansion of the tumor following treatment is increased with larger tumors. The severity of the neurologic deficits associated with the pituitary tumor is the clinically most relevant prognostic indicator.

External beam radiotherapy has been used for pituitary tumors associated with pituitary-dependent hyperadrenocorticism. In general the neurologic signs improve more rapidly than the endocrinologic signs. There can be dramatic reduction in tumor size, but no long-term survival studies have been reported. With the availability of effective drugs to treat hypercortisolemia, radiotherapy should probably be considered only in cases of hyperadrenocorticism with neurologic signs. Treatment protocols vary among centers and need to be tailored to the individual patient.

TREATMENT OF ADRENAL-DEPENDENT HYPERADRENOCORTICISM

When treating adrenal-dependent hyperadrenocorticism, owners can opt for a high-risk surgical strategy with a potentially excellent but possibly disastrous outcome or a low-risk medical strategy with a more predictable but less positive outcome. Accurate imaging is essential in informing this decision. Good communication between the veterinarian and client is essential when owners of dogs with hyperadrenocorticism are deciding which strategy is the most appropriate for them and their animal.

Surgical Options

Unilateral adrenalectomy is indicated for adrenal-dependent hyperadrenocorticism, but careful owner counseling is important since this form of hyperadrenocorticism may also be managed medically. The extent of any local invasion or metastatic spread should be investigated before surgery is performed.

Preoperative stabilization probably improves survival, but this has not been clearly demonstrated. Mitotane may be less useful than trilostane or ketoconazole in this respect because it may make the tumor more friable.

Medical Options

Mitotane

The cytotoxic properties of mitotane make it the logical choice for the long-term medical management of canine adrenal-dependent hyperadrenocorticism. Tumor regression has been demonstrated in some cases; however, most adrenal tumors are relatively resistant to the cytotoxic effects. This means that, when compared to dogs with pituitary-dependent hyperadrenocorticism, dogs with adrenal-dependent hyperadrenocorticism are more variable in their response to mitotane. They may respond very quickly to normal doses, or they may require prolonged induction courses of mitotane at increased

doses. Therefore careful patient monitoring is essential. Even if the response to an ACTH stimulation test was normal at the onset of treatment, the test can still be used to monitor mitotane therapy since the aim is to reduce the post-ACTH cortisol to less than 120 nmol/L (4.3 mcg/ml). A starting dosage of 50 mg/kg orally every 24 hours should be given. However, if there is no improvement in clinical signs or if the ACTH stimulation test results have not been suppressed after 10 days, the dosage can be increased to 75 mg/kg orally every 24 hours.

Relapses are common during maintenance therapy. Furthermore, dogs may develop signs of mitotane toxicity (such as vomiting, anorexia and diarrhea) without control of cortisol production having been achieved.

Trilostane

Only one case of long-term trilostane treatment of a dog with adrenal-dependent hyperadrenocorticism has been reported. However, amelioration of clinical signs, a reduction in post-ACTH cortisol concentrations, and improvement of clinical pathologic parameters, as well as extended survival times (more than 2 years) have been achieved in several cases (our and others' unpublished observations). Furthermore, median survival of dogs with adrenal-dependent hyperadrenocorticism treated with trilostane seems comparable to that of dogs treated with mitotane (our unpublished studies). Although trilostane is not cytotoxic and thus has no effect on the growth of the tumor or of metastases, experience has shown that the same recommendations in dogs with adrenal-dependent hyperadrenocorticism are valid as for dogs with pituitary-dependent hyperadrenocorticism. Interestingly, the doses required to achieve clinical stabilization do not seem to increase significantly with time in dogs that do respond to the initial therapy.

Adrenal Insufficiency in Critical Illness

JENNIFER E. PRITTIE, *New York, New York*

Relative adrenal insufficiency is a transient inability of the adrenal glands to mount an appropriate cortisol response to severe stress or illness. This syndrome has been well documented in septic human patients, contributing to the development of refractory hypotension and death. Administration of supraphysiologic steroids in affected patients leads to rapid shock reversal and decreased mortality. This chapter reviews the incidence, characteristics, diagnosis, and treatment of adrenal insufficiency in critically ill humans and provides a brief overview of available comparative data concerning pituitary-adrenal function in critically ill dogs or cats.

THE ROLE OF CORTISOL IN HEALTH AND DISEASE

Activation of the hypothalamic-pituitary-adrenal (HPA) axis in response to acute illness or injury is paramount for maintenance of homeostasis and adaptation during periods of severe stress. Cortisol, the predominant glucocorticoid produced by the adrenal cortex, plays an important role in maintenance of normal endothelial integrity, vascular permeability, and distribution of total body water. This hormone affects vascular tone by increasing the number and improving the function of α - and β -adrenergic receptors as well as via inhibition of nitric oxide production. Cortisol improves myocardial contractility and attenuates the down-regulation of adrenergic receptors that occurs secondary to catecholamine therapy in septic shock. In addition, cortisol modulates immune-mediated inflammation via inhibition of leukocyte migration, neutrophil and endothelial adhesion, and macrophage and endothelial function.

Among other physiologic stressors, severe illness, trauma, and surgery result in profound activation of the HPA axis with a resultant increase in circulating corticotropin (ACTH) and cortisol concentrations. The magnitude of the increase in serum cortisol concentration has been correlated positively with both illness severity and mortality.

ADRENAL INSUFFICIENCY IN HUMANS WITH CRITICAL ILLNESS

Absolute Adrenal Insufficiency

Absolute adrenal insufficiency can be primary, resulting from destruction of the adrenal glands (Chapter 51), or secondary to disorders affecting the hypothalamus or

pituitary gland. Patients suffering from absolute adrenal insufficiency demonstrate a low basal cortisol concentration that responds minimally or not at all to stimulation with ACTH. This syndrome is rare in humans with critical illness, affecting approximately 2% to 5% of intensive care unit (ICU) patients.

Relative Adrenal Insufficiency

In a subset of critically ill patients, normal or increased basal cortisol concentrations are inadequate *relative* to the increased demand during periods of extreme stress. These patients have limited adrenal reserve, with an insufficient cortisol response to combat ongoing inflammation or infection, and they exhibit blunted responses to exogenous ACTH stimulation *independent* of basal cortisol values (which are often high in absolute terms at the onset of the septic episode). This “relative adrenal insufficiency” is functional as opposed to structural and is transient in nature, resolving following recovery from illness. Depending on the criteria used for diagnosis, relative adrenal insufficiency affects approximately 10% to 50% of all critically ill humans with sepsis.

Causes of Relative Adrenal Insufficiency in Critical Illness

The cause of relative adrenal insufficiency is unknown, but the development of this syndrome in septic patients is most likely multifactorial, involving a complex interaction between endocrine and immune systems. Various cytokines circulating during systemic infection (e.g., tumor necrosis factor- α) inhibit ACTH-releasing hormone and ACTH and directly impair adrenal function. Leptin and corticostatin, peptides produced by adipocytes and immune cells, respectively, also circulate in high concentrations in septic patients. These peptides impair adrenocortical function and may contribute to the development of relative adrenal insufficiency.

Clinical and Laboratory Features of Relative Adrenal Insufficiency in Critical Illness

Impairment of the normal cortisol response during critical illness can result in hypotension that mimics either hypovolemic shock (characterized by decreased preload and increased systemic vascular resistance) or septic/hyperdynamic shock (characterized by increased cardiac output and decreased systemic vascular resistance). Hemodynamic instability with hypotension refractory to fluid and vasopressor therapy is common in humans

with relative adrenal insufficiency. Additional clinical features suggestive of this syndrome include weakness, fatigue, gastrointestinal disturbances (nausea, vomiting, and anorexia), and fever. Compatible laboratory findings include hypoglycemia, hyponatremia, and hyperkalemia (infrequently reported in relative adrenal insufficiency). Absolute or relative eosinophilia has also been reported.

Because clinical signs are vague and nonspecific, relative adrenal insufficiency can be challenging to diagnose clinically. Index of suspicion should be particularly high in critically ill patients who exhibit refractory hypotension, who are unable to be weaned from mechanical ventilation, or who have ongoing inflammation with no obvious source.

Definitive Diagnosis of Relative Adrenal Insufficiency in Critical Illness

Biochemical evaluation of adrenal function typically involves administration of the ACTH stimulation test. This test bypasses the hypothalamic-pituitary axis and assesses only the integrity of the adrenal gland. Traditionally a total dosage of 250 mcg of synthetic ACTH is administered intravenously (IV) to a human or dog, whereas cats received a total dosage of 125 mcg. Serum or plasma cortisol concentration is measured before, 30 minutes after, and/or 60 minutes after ACTH administration. Low basal and ACTH-stimulated cortisol concentrations are consistent with a diagnosis of absolute adrenal insufficiency. A blunted response to ACTH stimulation, irrespective of basal cortisol concentration (which is typically high), is suggestive of relative adrenal insufficiency.

Several factors complicate the evaluation of adrenal function in critically ill patients. First, there is marked heterogeneity in basal and ACTH-stimulated cortisol concentrations in sick patients. Reference ranges for the standard ACTH stimulation test in both humans and animals were established by use of healthy control subjects, and it is likely that inaccuracy will be introduced if these normal values are applied to ICU patients.

Second, laboratory criteria that are used to diagnose relative adrenal insufficiency are controversial. To improve the usefulness of the ACTH stimulation test in humans with critical illness, it has been recommended that defining threshold cortisol levels below which relative adrenal insufficiency is likely and above which relative adrenal insufficiency is unlikely may be more appropriate in this patient population (Cooper and Stewart, 2005). For patients with random cortisol measurements between such low and high values, response to ACTH stimulation can be used to assess adrenal reserve and identify patients who may benefit from corticosteroid administration.

Other investigators advocate the change in serum cortisol following ACTH stimulation (i.e., the delta cortisol) as the primary diagnostic criterion for this syndrome of relative adrenal insufficiency. Using a cortisol response of less than or equal to 9 mcg/dl, over half of humans with sepsis had relative adrenal insufficiency in one study (Annane et al., 2000). As with basal cortisol, the incremental cortisol response following ACTH administration, or the delta cortisol, has been shown to vary inversely with illness severity and mortality in humans. A third factor that may confound the diagnosis of relative adrenal

insufficiency in critically ill patients is the dose of ACTH used in test subjects. The standard ACTH stimulation test (250 mcg total dosage per patient) involves administration of supraphysiologic doses of ACTH, far surpassing the endogenous ACTH level achieved following normal stress-induced release. This large dose of ACTH may result in a normal cortisol response despite adrenal ACTH resistance and lack of adequate adrenal reserve. Use of a low-dose (1-mcg) ACTH stimulation test may be more sensitive than the 250-mcg test in documentation of relative adrenal insufficiency, but further validation is warranted before acceptance of this test in the clinical setting.

Treatment of Relative Adrenal Insufficiency in Patients With Critical Illness

Prompt recognition of relative adrenal insufficiency in critically ill patients can have dramatic effects on patient morbidity and mortality. High basal cortisol concentration and a blunted response to ACTH stimulation identify not only patients with a higher risk of death but also those who might benefit from corticosteroid therapy. Additional therapies for relative adrenal insufficiency include underlying disease eradication and general supportive measures designed to optimize end-organ perfusion.

There are several randomized, controlled trials of glucocorticoid replacement in human septic shock patients suspected of having relative adrenal insufficiency. Most clinical trials have demonstrated more rapid shock reversal (i.e., ability to wean from vasopressor support) in patients administered supraphysiologic steroids versus placebo. In addition, a recent trial evaluating 300 humans with septic shock showed a survival advantage associated with concurrent administration of glucocorticoids and mineralocorticoids versus placebo (Annane, 2002). Mineralocorticoid deficiency in critically ill humans has been documented in several studies, but the value of aldosterone replacement in these patients is unclear at this time.

Supraphysiologic glucocorticoid administration in patients suspected of having relative adrenal insufficiency has also been efficacious in critically ill human trauma and surgical patients. Steroid administration in these patients was associated with rapid cessation of vasopressor therapy, ability to wean from ventilatory support, and fever resolution.

The role of glucocorticoids in treatment of septic shock has long been debated. Most investigators have reported that short-term administration of pharmacologic steroids (methylprednisolone, 30 mg/kg IV) is of no benefit and may be harmful (because of pronounced immunosuppressive effects) in septic humans. Therefore it is currently strongly recommended that high-dose steroids not be administered to these patients. Conversely, a more prolonged course of "low-dose" glucocorticoids (100 mg, or approximately 1.5 mg/kg, of hydrocortisone every 6 to 8 hours IV) can be recommended for humans suffering from refractory septic shock. The recommendation was included in the 2004 Surviving Sepsis Campaign guidelines.

The glucocorticoid dose currently recommended for relative adrenal insufficiency is supraphysiologic, resulting in

a plasma cortisol concentration several times higher than that achieved via ACTH stimulation. This regimen of therapy was initially based on the maximum secretory rate of cortisol found in humans following major surgery (i.e., 300 mg of hydrocortisone per day). However, the optimal dose and duration of treatment with steroids has yet to be determined.

Which patients may benefit from supraphysiologic steroid administration and when to initiate this therapy are also unclear. Clinical signs of relative adrenal insufficiency may be subtle and vague, and definitive diagnosis is difficult to achieve with available biochemical tests. The question remains: does response to ACTH stimulation in critically ill patients predict response to steroid therapy? Debate persists regarding the appropriateness of steroid administration without laboratory confirmation of adrenal dysfunction.

A recent clinical trial documented a trend, albeit insignificant, toward increased mortality in "responders" to ACTH stimulation who received supplemental steroids during the study period (Annane, 2002). This finding may refute the argument that response to treatment is an appropriate diagnostic test for relative adrenal insufficiency. The current recommendation in humans is to initiate steroid treatment in patients suffering from refractory shock pending diagnostic confirmation of adrenal dysfunction. This treatment is withdrawn if there is no laboratory evidence of adrenal insufficiency (absolute or relative).

RELATIVE ADRENAL INSUFFICIENCY IN DOGS AND CATS

To date there are limited data evaluating the HPA axis in critically ill animals, and the incidence of relative adrenal insufficiency in these patients is largely unknown. Investigators have documented adrenal dysfunction in experimental rat models of severe hemorrhage and sepsis, suggesting the presence of relative adrenal insufficiency in these subjects. Prittie and colleagues (2003) evaluated adrenocortical function in 20 critically ill cats. Basal cortisol concentrations were higher in sick versus healthy cats but did not correlate with outcome in this population. Similarly, ACTH-stimulated and delta cortisol had no prognostic value in these cats. Cats with neoplasia, but not cats with sepsis, demonstrated lower delta cortisols than did other patients in this study population, suggesting that relative adrenal insufficiency may occur in this subset of critically ill cats. Farrelly and associates (1999) similarly documented adrenal dysfunction in cats with lymphosarcoma, based on blunted cortisol responses to ACTH stimulation. None of these cats had cytologic or histopathologic confirmation of normal adrenal structure, but ultrasound measurements of adrenal size were within normal limits. Relative adrenal insufficiency has recently been reported in a cat recovering from polytrauma and being treated for suspected sepsis (Durkan, 2007). This patient exhibited vasopressor-dependent hypotension that resolved following supraphysiologic steroid administration, and a blunted response to ACTH stimulation (i.e., a delta cortisol of 3.2 mcg/dl).

The occurrence of relative adrenal insufficiency in dogs remains to be determined. One study evaluated pituitary-adrenal function in critically ill dogs through daily ACTH stimulation tests during ICU hospitalization (Prittie and colleagues, 2002). No dog developed relative adrenal insufficiency during the study period; basal cortisol and ACTH-stimulated cortisol concentrations remained within or above the reference range established for healthy dogs. Basal cortisol concentration did not correlate with illness severity or outcome in these dogs, unlike the case in many human studies. Delta cortisol was not evaluated. More recently adrenal function was examined retrospectively in 42 sick dogs (Shaw and associates, 2005). Four dogs demonstrated adrenal dysfunction characterized by low basal and delta cortisol levels, and all were nonsurvivors. However, there was not a clear delineation between absolute and relative adrenal insufficiency in that study population.

Given the paucity of information available regarding the occurrence of relative adrenal insufficiency in critically ill small animals, currently there are no guidelines for diagnosis and treatment of this disorder. As is the case with human ICU patients, a high index of suspicion of relative adrenal insufficiency is warranted in critically ill veterinary patients that are volume loaded and remain vasopressor dependent. This is especially the case in cats with cancer that have been shown to have evidence of adrenal dysfunction. Relative adrenal insufficiency in these cats may explain the dramatic clinical response to glucocorticoid administration that precedes implementation of chemotherapy. If clinical suspicion of relative adrenal insufficiency is high, supraphysiologic glucocorticoid replacement pending results of confirmatory laboratory tests seems prudent.

Hypoadrenocorticism

PETER P. KINTZER, *Springfield, Massachusetts*

MARK E. PETERSON, *Bedford Hills, New York*

Spontaneous canine hypoadrenocorticism is a well-recognized but uncommon endocrine disorder. Hypoadrenocorticism is characterized by a deficiency of glucocorticoid and/or mineralocorticoid production by the adrenal cortices. Although mild destruction or atrophy of adrenocortical tissue can impair adrenocortical reserve, typically at least 90% of the adrenal cortex needs to be nonfunctional before clinical signs of hypoadrenocorticism are observed under nonstressful conditions.

ETIOLOGY

Primary hypoadrenocorticism results from destruction or atrophy of the adrenal cortices and usually results in a deficiency of both glucocorticoid and mineralocorticoid secretion. Causes include idiopathic spontaneous (probably immune-mediated) primary hypoadrenocorticism (Addison's disease), iatrogenic disease resulting from mitotane or trilostane therapy, and very rare cases of adrenocortical destruction resulting from granulomatous disease, metastatic neoplasia, or hemorrhage.

A subset of dogs with primary hypoadrenocorticism appear to develop a selective glucocorticoid deficiency with apparently normal mineralocorticoid secretion, based on the findings of low basal and adrenocorticotropin hormone (ACTH)-stimulated serum cortisol values with normal concentrations of serum electrolytes. This type of hypoadrenocorticism is commonly referred to as "atypical" hypoadrenocorticism. In most of these dogs mineralocorticoid deficiency eventually develops, but a few dogs do not develop deficient mineralocorticoid secretion or serum electrolyte changes when followed for many months or years.

Secondary hypoadrenocorticism is caused by insufficient pituitary ACTH production and the resultant atrophy of the portion of the adrenal cortices responsible for glucocorticoid production. The result is deficient glucocorticoid secretion; mineralocorticoid secretion is preserved. Causes include iatrogenic disease resulting from overly rapid discontinuation of long-term and/or high-dose glucocorticoid therapy, pituitary or hypothalamic lesions, or idiopathic isolated ACTH deficiency.

DIAGNOSIS

Although most affected dogs present in young to middle age, naturally occurring hypoadrenocorticism has been reported in dogs ranging from 2 months to 14 years of age. A genetic predilection has been confirmed in standard poodles and bearded collies and suggested in certain breeds

such as Nova Scotia duck tolling retrievers, Leonbergers, Portuguese water spaniels, Great Danes, rottweilers, and wheaten and West Highland white terriers. Female dogs are about twice as likely to develop naturally occurring hypoadrenocorticism as males.

The historical findings, clinical signs, and laboratory abnormalities associated with spontaneous hypoadrenocorticism are well described (Tables 51-1 and 51-2). The severity and duration of clinical signs vary greatly among cases, from the acute life-threatening addisonian crisis to the chronic intermittent signs seen in some dogs with chronic hypoadrenocorticism. Many of the historical and clinical findings are nonspecific and also occur in many more common diseases, particularly gastrointestinal and renal disorders. No set of findings is pathognomonic for canine hypoadrenocorticism. A high index of suspicion is needed to recognize some cases. Findings that should heighten this suspicion include a waxing/waning course, previous response to fluid or glucocorticoid therapy, and exacerbation of clinical signs in stressful situations.

The classic electrolyte abnormalities associated with spontaneous primary hypoadrenocorticism are hyperkalemia and hyponatremia. In our experience one or both are present in 90% to 95% of affected dogs. Prior treatment with fluids, steroids, or both may mask serum electrolyte changes. Therefore one should never exclude a diagnosis of primary hypoadrenocorticism in a dog suspected of having hypoadrenocorticism on a basis of normal serum electrolyte concentrations alone. Also, some dogs with secondary hypoadrenocorticism caused by isolated pituitary ACTH deficiency are hyponatremic with normal potassium concentrations. Although Addison's disease is often the first disorder thought of when these electrolyte abnormalities are found, the presence of hyperkalemia and hyponatremia cannot be relied on for the diagnosis of canine hypoadrenocorticism. Indeed these electrolyte abnormalities may be associated with a wide variety of diseases more common than hypoadrenocorticism, including gastrointestinal disorders, renal disease, effusive disorders, and acidosis.

Definitive diagnosis of hypoadrenocorticism requires demonstration of inadequate adrenal reserve. This is done by performing an ACTH stimulation test, considered the gold standard for diagnosis of hypoadrenocorticism. The preferred method is to determine serum cortisol concentrations before and 1 hour after the intravenous administration of 5 mcg/kg of cosyntropin (Cortrosyn, Amphastar Pharmaceuticals, Rancho Cucamonga, CA). Following reconstitution, the solution, when refrigerated, is stable

Table 51-1

Clinical Findings in Dogs With Hypoadrenocorticism

Finding	Percent
Lethargy/depression	95
Anorexia	90
Vomiting	75
Weakness	75
Weight loss	50
Dehydration	45
Diarrhea	40
Waxing/waning course	40
Collapse	35

ALT, Alanine aminotransferase; AST, aspartate aminotransferase

for at least 4 weeks. Otherwise the remaining solution can be divided into aliquots and frozen.

If cosyntropin is not available, the ACTH stimulation test can also be performed by determining the serum cortisol concentration before and after the intramuscular injection of 2.2U/kg of ACTH gel. Acthar Gel (80U/ml; Questor Pharmaceuticals, Union City, CA) is available but very expensive. If this product is used, the post-ACTH sample is collected at 2 hours. Alternatively ACTH gel (usually 40U/ml) is available from several compounding pharmacies. The bioavailability and reproducibility of all

of these formulations have yet to be carefully evaluated. A recent study in dogs by Kemppainen, Behrend, and Busch (2005) using four compounded ACTH gels demonstrated increases in serum cortisol concentrations comparable to cosyntropin injection 1 hour after intramuscular injection of each of the four formulations but considerable variation at 2 hours after injection. The investigators recommended determining serum cortisol concentrations at both 1 and 2 hours post-ACTH administration when using a compounded ACTH gel. The determination of a third cortisol level would likely offset any presumed cost saving derived from using the compounded product. The potential for lot-to-lot variability in compounded ACTH gel formulations has not been evaluated. Therefore one should consider assessing the activity of each new vial by performing an ACTH stimulation test on a normal dog.

In normal dogs administration of a supraphysiologic dose of ACTH produces a rise in serum cortisol to values usually above 10mcg/dl. In contrast, dogs with hypoadrenocorticism have an absent or blunted response to ACTH administration. Basal and post-ACTH serum cortisol concentrations are less than 1mcg/dl in over 75% of dogs and less than 2mcg/dl in virtually all dogs with primary hypoadrenocorticism. Although the post-ACTH serum cortisol concentration may be as high as 2 to 3mcg/dl in a few dogs with secondary hypoadrenocorticism, the great majority of these dogs also have ACTH-stimulated cortisol concentrations of less than 2mcg/dl.

The ACTH stimulation test using intravenous cosyntropin can be performed during institution of initial treatment if dexamethasone is used for glucocorticoid replacement since dexamethasone does not interfere with the cortisol assay. If prednisone, prednisolone, or hydrocortisone have been administered, these treatments must be discontinued, and glucocorticoid supplementation changed to dexamethasone for at least 24 hours before ACTH stimulation testing. ACTH gel cannot be used in dehydrated or hypovolemic patients since impaired absorption may lead to inaccurate results. Alternatively, testing can be delayed until after the patient is stabilized.

A recent study in dogs comparing an in-house cortisol assay (SNAP Cortisol, IDEXX Laboratories, Westbrook, ME) with a reference laboratory chemiluminescent assay showed very positive correlation between the two assays. The in-house assay is particularly useful when a rapid determination of the presence of hypoadrenocorticism is desired, such as differentiating in an emergency patient between an Addisonian crisis and a disease with a poorer prognosis such as acute renal failure.

Secondary hypoadrenocorticism can be differentiated from atypical primary hypoadrenocorticism by measurement of a plasma ACTH level. Plasma ACTH is high (>500pg/ml) with primary hypoadrenocorticism and undetectable-to-low with secondary hypoadrenocorticism. ACTH is labile; therefore the diagnostic laboratory performing the assay should be consulted for appropriate sample handling instructions. Plasma for ACTH determination must be collected before instituting therapy, especially glucocorticoid treatment. Even a relatively low dose of glucocorticoid may reduce previously-high ACTH concentrations into the normal-to-low reference range; thus the results must be interpreted in conjunction with a

careful drug history. To properly evaluate the endogenous ACTH test result, the dog ideally should not have received any form of steroid treatment in the preceding weeks. If plasma ACTH is measured in a dog that has received recent glucocorticoid treatment, a false-positive diagnosis of secondary hypoadrenocorticism may be entertained.

Recently an alternate approach was proposed in dogs for assessing the pituitary-glucocorticoid axis by measuring basal cortisol and plasma ACTH concentrations and then calculating a cortisol-to-ACTH ratio (Javadi and colleagues, 2006). Similarly the renin-angiotensin-aldosterone system was assessed by determining the basal plasma concentrations of aldosterone and plasma renin activity and then calculating an aldosterone-to-renin ratio.

Dogs with primary hypoadrenocorticism have low basal concentrations of cortisol with high plasma ACTH concentrations. In contrast, dogs with secondary hypoadrenocorticism have low plasma cortisol concentrations with low plasma ACTH concentrations. Therefore dogs with primary hypoadrenocorticism have much lower cortisol-to-ACTH ratios than do normal dogs or dogs with secondary hypoadrenocorticism, with little to no overlap in ratio values.

In states of aldosterone deficiency such as primary hypoadrenocorticism, the inability to retain sodium leads to hypovolemia, which subsequently stimulates renin release. Thus dogs with primary hypoadrenocorticism have low basal concentrations of aldosterone with high plasma renin activity. In secondary hypoadrenocorticism aldosterone secretion is not decreased; therefore plasma renin activity remains relatively normal. Accordingly, dogs with primary hypoadrenocorticism have much lower aldosterone-to-renin ratios than do normal dogs or dogs with secondary hypoadrenocorticism, again with little to no overlap in ratio values.

The advantage of the use of cortisol-to-ACTH and aldosterone-to-renin ratios is that such measurement of endogenous hormone variables in a single blood sample allows for the specific diagnosis of primary hypocortisolism and primary hypoaldosteronism. A dynamic stimulation test is not required. The use of these paired-hormone ratios generally allows for clear differentiation between primary and secondary hypoadrenocorticism; this dual assessment is particularly relevant when isolated hormone deficiency is suspected (i.e., isolated glucocorticoid deficiency or isolated mineralocorticoid deficiency).

Disadvantages of this approach to diagnosis include the considerable expense to measure plasma concentrations of cortisol, ACTH, aldosterone, and renin activity, as well as sample handling, including the absolute necessity of collecting blood for measurement of hormone and renin concentrations before any fluid or steroid treatment. Furthermore, it may be difficult to find a laboratory that can accurately measure plasma renin activity in dogs.

TREATMENT

The intensiveness of therapeutic intervention depends on the individual patient's condition. Acute hypoadrenocorticism (addisonian crisis) is a medical emergency

requiring prompt treatment, whereas dogs with chronic hypoadrenocorticism generally do not need aggressive therapy, although many may benefit from hospitalization for parenteral fluids and glucocorticoids.

Acute Hypoadrenocorticism

If the clinical presentation is consistent with an addisonian crisis, treatment must be instituted immediately once blood is collected for a complete blood count, chemistry profile, and other indicated laboratory work and urine obtained for urinalysis. Definitive diagnostic workup is begun while initial treatment and stabilization is in progress. Goals of therapy are to restore plasma volume status, correct electrolyte and acid-base disturbances, improve vascular integrity, and provide an immediate source of rapid-acting glucocorticoid.

Of primary importance in therapy for acute hypoadrenocorticism is the rapid infusion of large volumes of intravenous fluids, preferably 0.9% NaCl, at an initial rate of 60 to 80 ml/kg/hour for 1 to 2 hours. This initial rate of infusion helps to address hypotension and hypovolemia. In addition, serum potassium concentration is reduced by dilution, increased renal perfusion, and thereby potassium excretion. A colloid also can be administered to address hypotension and hypovolemia, but this is rarely needed. The rate of saline infusion is then gradually reduced to a maintenance rate and eventually discontinued over a few days based on the dog's clinical response and laboratory parameters, including serial blood pressure, renal function, and electrolyte measurements. Urine output should be quantified to assess its adequacy and to help guide fluid therapy. If severe hyponatremia is present on initial evaluation, it should be corrected no faster than 10 to 12 mEq/dl per day over the first 48 hours of therapy. Overly rapid correction of hyponatremia can result in neurologic damage (myelinosis).

Also critically important to the therapy of acute hypoadrenocorticism is the intravenous administration of a rapid-acting glucocorticoid. Dexamethasone sodium phosphate (2 to 4 mg/kg) or prednisolone sodium succinate (15 to 20 mg/kg) is preferred; dexamethasone sodium phosphate must be used if the ACTH stimulation test is in progress. This initial dose of dexamethasone can be repeated in 2 to 6 hours if needed. Glucocorticoid supplementation is then gradually tapered to a maintenance dose of prednisone (0.2 mg/kg) over the next several days as dictated by clinical response. The maintenance dose of prednisone may not be reached until after the patient is at home. Parenteral supplementation is indicated until vomiting has ceased and oral intake has begun.

Hyperkalemia is often successfully corrected by parenteral fluid therapy alone. However, for severe hyperkalemia causing life-threatening myocardial toxicity manifested by significant arrhythmias (including atrial standstill, abnormal ST-T waves, and widening of the QRS complex), more aggressive therapy is necessary. Our preferred treatment is intravenous insulin and dextrose. Regular insulin (0.5 U/kg) is given intravenously. Glucose (2 to 3 g/U of insulin) is given half as an intravenous bolus and half in the intravenous fluids over the next 6 to 8 hours. These dogs must be closely monitored for hypoglycemia, with hourly blood

glucose determinations. Dogs with hypoadrenocorticism are very sensitive to the glucose-lowering action of insulin; however, the administration of the rapid-acting glucocorticoid as described previously before or concurrent with insulin administration would be expected to counteract this tendency. Alternatively slow intravenous administration of 10% calcium chloride (0.1 ml/kg over 10 to 20 minutes) or NaHCO_3 (1-2 mEq/kg over 10-15 minutes) can be considered to treat advanced hyperkalemic myocardial toxicity.

Hypoglycemia and metabolic acidosis may demand treatment in some cases. Dextrose (2.5% to 5%) is added to the intravenous fluids as needed. Symptomatic hypoglycemia is treated with a slow intravenous bolus of 0.5 to 1.5 ml/kg of 50% dextrose. Mild-to-moderate acidosis is usually corrected with parenteral fluid therapy. Severe metabolic acidosis ($\text{pH} < 7.1$) is treated with sodium bicarbonate. The total dosage is calculated as follows:

$$\text{Deficit in mEq} = (\text{body weight in kilograms}) (0.5) \\ (\text{base deficit})$$

One fourth of the calculated dosage is administered in the intravenous fluids over the next 6 to 8 hours, and the acid-base status then reassessed. It is unusual for additional bicarbonate therapy to be needed.

No rapid-acting parenteral mineralocorticoid preparation is currently available for treatment of acute hypoadrenocorticism. This does not constitute a significant clinical problem because prompt aggressive treatment as described previously is sufficient to stabilize a dog suffering an addisonian crisis. Nonetheless we typically give a desoxycorticosterone pivalate (DOCP; Percorten-V, Novartis Animal Health, Greensboro, NC) injection as soon as the diagnosis of primary hypoadrenocorticism is confirmed. Alternatively, fludrocortisone acetate (Florinef, Bristol-Myers Squibb) can be used. Such mineralocorticoid supplementation is not harmful and may help correct serum electrolyte abnormalities.

Chronic Hypoadrenocorticism

Dogs with chronic hypoadrenocorticism present with clinical signs of varying severity and duration and do not require the aggressive therapy described previously for cases of acute hypoadrenocorticism. However, fluid therapy and parenteral glucocorticoid supplementation may be indicated in some cases, particularly if azotemia, dehydration, hypotension, or significant vomiting or diarrhea is present. In these dogs parenteral therapy is continued until these abnormalities have resolved and maintenance therapy can be instituted. Similarly, in dogs recovering from an addisonian crisis, maintenance therapy is instituted once the dog is stable and oral medication can be tolerated.

Dogs with naturally occurring primary hypoadrenocorticism typically require both glucocorticoid and mineralocorticoid replacement therapy for life. The few dogs with atypical primary hypoadrenocorticism can be started on glucocorticoid replacement therapy alone but must have serum electrolyte concentrations frequently monitored since most of these dogs will develop the typical

electrolyte abnormalities after weeks to months and require mineralocorticoid supplementation as well.

Either DOCP or fludrocortisone can be used for chronic mineralocorticoid replacement. We typically institute treatment with DOCP given at 2.2 mg/kg subcutaneously or intramuscularly every 4 weeks. Side effects associated with DOCP therapy are rare. A dosage interval of 3 to 4 weeks is effective in almost all cases, and most are controlled with an injection every 4 weeks. After the first one or two injections of DOCP, electrolyte and creatinine levels are monitored at 2, 3, and 4 weeks following injection to determine the duration of action and help make dosage adjustments if necessary. Once stabilized, serum electrolyte and creatinine concentrations are checked every 3 to 6 months.

Although a DOCP dose of less than 2.2 mg/kg would be sufficient in some cases, a dose of 2.2 mg/kg is still recommended at least for the initial treatment. Less than 10% of dogs require a DOCP dose greater than 2.2 mg/kg, and a starting dose of 2.2 mg/kg eliminates the need for the clinician to incrementally increase the DOCP dosage over the first several months of therapy, which often happens in dogs started on a lower initial DOCP dose. However, if financial constraints are a factor, one can attempt to gradually reduce the monthly dose of DOCP to the lowest effective dose based on close monitoring of serum electrolyte concentrations. Alternatively, the interval between DOCP injections can be incrementally lengthened (typically in 1-week intervals) as dictated by monitoring of serum electrolyte concentrations. Dogs with hypoadrenocorticism and congestive heart failure (such as some Rottweilers with dilated cardiomyopathy) may require higher doses of furosemide the first 2 weeks following DOCP administration to prevent pulmonary edema (fludrocortisone represents an alternative treatment for this group).

Fludrocortisone acetate is given at an initial oral dosage of 0.01 to 0.02 mg/kg/day, and the dosage is adjusted by 0.05 to 0.1 mg/day as determined by serial serum electrolyte concentrations. After initiation of fludrocortisone therapy, serum electrolyte and creatinine levels should be monitored until stabilized within the normal range. Once this is achieved, the dogs should be reevaluated monthly for the first 3 to 6 months of therapy and then every 3 to 6 months thereafter. In many dogs in which fludrocortisone is used as long-term mineralocorticoid replacement, the daily dose required to control the disorder gradually increases; this is most evident in the first 6 to 24 months of treatment. In most dogs the final fludrocortisone dosage needed is 0.02 to 0.03 mg/kg/day. Very few dogs can be controlled on a dosage of 0.01 mg/kg/day or less. Adverse effects (usually polyuria and polydipsia), development of a relative resistance to the effects of fludrocortisone, or financial considerations (especially when treating large- or giant-breed dogs) may necessitate a change to DOCP therapy in some dogs.

Many dogs with primary hypoadrenocorticism, particularly those receiving DOCP, require chronic glucocorticoid supplementation in addition to mineralocorticoid supplementation to prevent signs of glucocorticoid deficiency. In general, all dogs with primary hypoadrenocorticism are

started on glucocorticoid replacement with prednisone or prednisolone (0.2 mg/kg/day) in conjunction with mineralocorticoid replacement (usually DOCP). If warranted because of the development of side effects, the glucocorticoid dosage can be tapered to alternate days and then discontinued if necessary to evaluate if glucocorticoids are needed as part of maintenance therapy. The fact that glucocorticoids can be discontinued without the recurrence of significant clinical signs in some dogs with hypoadrenocorticism is especially important in dogs that have developed signs of intolerance of glucocorticoid administration (e.g., polyuria/polydipsia) after treatment. In many of these dogs cessation of glucocorticoids reverses signs of iatrogenic hyperadrenocorticism, and mineralocorticoid replacement alone controls signs of hypoadrenocorticism. Nevertheless, additional glucocorticoid supplementation (2 to 10 times normal recommended replacement dosage) may be necessary during periods of stress such as illness, trauma, or surgery; therefore the owner should always have some glucocorticoid on hand and be informed of situations in which the dog might require glucocorticoid supplementation. Dogs with documented secondary hypoadrenocorticism (isolated pituitary ACTH deficiency) require only glucocorticoid replacement therapy. Oral administration of prednisone or prednisolone at a dosage of 0.2 mg/kg/day usually suffices, except during periods of stress or illness when higher doses are necessary. If secondary hypoadrenocorticism has not been documented by the presence of undetectable-to-low plasma ACTH concentrations in hypoadrenal patients with normal serum electrolyte concentrations, one must continue to determine serum electrolyte concentrations on a regular

(e.g., monthly) basis. As mentioned previously, many dogs with atypical primary hypoadrenocorticism originally presenting with normal serum electrolyte concentrations and suspected of having secondary hypoadrenocorticism and being managed with only glucocorticoid supplementation will subsequently develop the typical electrolyte abnormalities of primary hypoadrenocorticism and require mineralocorticoid replacement therapy.

Idiopathic Feline Hypercalcemia

DENNIS J. CHEW, *Columbus, Ohio*

PATRICIA A. SCHENCK, *Lansing, Michigan*

Since the early 1990s unexplained hypercalcemia has been recognized increasingly as an incidental finding in cats and has been termed *idiopathic hypercalcemia (IHC)* is defined as abnormally elevated serum ionized calcium (iCa) concentration, the cause of which remains unknown after extensive medical evaluation to rule out known causes of hypercalcemia. Little is known about this syndrome, even though it appears to be the most common cause of hypercalcemia in cats. Although once thought to be a local geographic phenomenon, it is widespread across the United States, and anecdotal reports are emerging from other parts of the world (England, Scandinavia, Switzerland).

DIFFERENTIAL DIAGNOSIS

Hypercalcemia is typically noted on an initial analysis of serum total calcium (tCa) and is often a fortuitous discovery when a blood sample is taken for other reasons (e.g., wellness examinations, preanesthesia screening, evaluation of urolithiasis, evaluation of gastrointestinal signs). When a mild increase in serum tCa is noted, a second sample collected after a 12-hour fast should be submitted to verify the increase. If this mild increase in tCa is repeatable, an iCa measurement should be obtained. If a moderate or severe elevation in tCa is noted initially, iCa concentration should be measured as soon as possible. Serum iCa concentration needs to be measured because the prediction of iCa status from tCa measurement is not accurate.

Hypercalcemia may be parathyroid independent or parathyroid dependent (primary hyperparathyroidism). In parathyroid-independent hypercalcemia, the elevation of iCa results in *suppression* of parathyroid hormone (PTH) production. In cats with IHC, PTH values are usually normal to low normal (see below).

There are many potential causes of hypercalcemia in the cat (Box 52-1). A differential diagnostic list ensures that all possibilities for the development of hypercalcemia have been considered. However, such a list does not give any indication as to the frequency of the diagnoses. The most common diagnoses in cats with persistent elevations in iCa are idiopathic hypercalcemia (IHC) and malignancy. Renal failure often is accompanied by elevations in serum tCa, but iCa is rarely elevated in this condition. In many cases the diagnosis is obvious on analysis of history and physical examination. In others the cause may not be evident; and further workup, including hematology, serum biochemistry, body cavity imaging, cytology, and histopathology is necessary. A diagnosis of IHC is made when all other causes of hypercalcemia are

excluded. It should be noted that while IHC is the most frequent diagnosis in cats with hypercalcemia, it is an exceedingly uncommon finding in dogs following adequate diagnostic workup (see Chapter 54).

The magnitude of elevation of serum tCa cannot be used to make a diagnosis since there is considerable overlap in the degree of hypercalcemia in cats with IHC or other conditions. IHC may present with mild increases in tCa concentration (11 to 12 mg/dl; 2.75 to 3.00 mmol/L), whereas some cats may have tCa concentrations greater than 15 to 20 mg/dl (3.75 to 5 mmol/L).

CLINICAL PRESENTATION

Cats with IHC may have persistent elevations in iCa for months without apparent clinical signs, and no relationship has been noted between the magnitude of elevation and occurrence of clinical signs. In a review of 427 cats with IHC, the mean age at presentation was 9.8 years (range 0.5 to 20 years old), and long-haired cats were overrepresented (27% of cases). Both genders were equally represented. Almost half of the cats had no clinical signs (46%), 18% had mild weight loss, 6% had inflammatory bowel disease, 5% had chronic constipation, 4% presented with vomiting, and 1% were anorectic. Uroliths were reported in 15% of cats with IHC, and calcium oxalate stones were specifically present in 10% of cases.

Serum iCa was increased, and PTH concentration was in the lower half of the reference range (reference range 0 to 4 mmol/L) in our study. Concentrations of both ionized magnesium and 25-hydroxyvitamin D were within the reference range in most cats. In a small number of cats with IHC in which calcitriol (1,25-dihydroxyvitamin D) was measured, the calcitriol concentration was suppressed in most. Some cats with IHC develop chronic renal failure (CRF) secondary to the persistent hypercalcemia, and cats with CRF may develop IHC over time. A few cats may have both CRF and IHC on initial presentation. Serum phosphorus is usually in the normal range in cats with IHC unless it is increased as a result of concurrent CRF. Urinary specific gravity typically is within the reference range, and it appears that many cats with hypercalcemia can still maximally concentrate their urine if they do not have concurrent CRF.

TREATMENT

The treatment of hypercalcemia usually targets the dysregulated mechanisms that are responsible; however, in IHC these mechanisms remain unknown. Thus treatments at this time are empiric.

Box 52-1

**Differential Diagnosis of Hypercalcemia:
HARDIONS Eponym**

- H*: Hyperparathyroidism (1°, 3°, hyperplasia), HHM, houseplants, hyperthyroid
- A*: Addison's disease, aluminum toxicity, vitamin A, milk-alkali
- R*: Renal disease, raisins (grapes)—dogs
- D*: Vitamin D toxicosis (granulomatous Dz), drugs, calcipotriene (Dovonex), dehydration, DMSO (calcinosis cutis), diet
- I*: Idiopathic (cats), infectious, inflammatory, immobilization
- O*: Osteolytic (osteomyelitis, immobilization, local osteolytic hypercalcemia, bone infarct)
- N*: Neoplasia (HHM and LOH), nutritional
- S*: Spurious, schistosomiasis, salts of calcium, supplements

DMSO, Dimethylsulfoxide; *HHM*, humoral hypercalcemia of malignancy; *LOH*, local osteolytic hypercalcemia.

Should All Cats With IHC Receive Treatment?

Minor elevations in serum iCa concentrations are often ignored since many of these cats have mild or no apparent clinical signs. This mild elevation of calcium may increase gradually or remain at the initial increased level for long periods of time. Excess calcium is toxic to cells, particularly in the central nervous system, gastrointestinal tract, heart, and kidneys. Mineralization of soft tissues is an important complication, and the serum phosphorus concentration when hypercalcemia develops is important in determining the extent of mineralization. When the calcium (mg/dl) times phosphorus (mg/dl) product is greater than 60, soft-tissue mineralization is most severe. The need for therapy in IHC increases when iCa continues to elevate or clinical signs become more obvious (weight loss, depression, vomiting, constipation, urinary stones, emergence of CRF, development of less concentrated urine). The consequences of long-standing hypercalcemia can be devastating in those that develop CRF or urolithiasis, and aggressive treatment for hypercalcemia is warranted in these cases. Continued elevation of iCa leads to further development of renal lesions and development of new stones. An algorithm for decision to treat is presented in Fig. 52-1. Treatment plans for hypercalcemia that is increasing are presented in Figs. 52-2 and 52-3.

Diet Therapy

Normocalcemia may be restored after a change to a different diet. High-fiber diets (e.g., Hill's W/D, Royal Canin HiFactor Formula, Purina One Advanced Nutrition Hairball, Eukanuba/Iams Optimum Weight Control) have been noted to restore normocalcemia in some cats with IHC and calcium oxalate urolithiasis. In five cats with IHC and calcium oxalate uroliths, normocalcemia returned when a higher-fiber diet that was similar to the original diet in terms of urinary acidification and magnesium restriction was fed. However, in another study

there was no beneficial effect of high-fiber diets in cats with IHC. The effects of fiber on intestinal absorption are complex and depend on the type and amount of fiber in the diet and the interactions with other nutrients in the diet. High-fiber diets may decrease intestinal transit time; however, most manufacturers increase the quantity of calcium in high-fiber diets to offset the potential for decreased absorption.

Veterinary diets designed for cats in renal failure (e.g., Eukanuba/Iams Multi-Stage Renal, Hills Science Diet K/D, Purina NF Formula, Royal Canin Renal LP, Royal Canin Modified Formula) have very different compositions than maintenance diets designed for feeding healthy cats; the feeding of a renal failure diet may result in normocalcemia in some cats with IHC. Most renal diets are less acidifying than maintenance diets and are low in calcium and phosphorus. Canned diets are generally more restricted in calcium than dry diets. The decreased consumption of calcium leads to a decrease in the amount of calcium absorbed, and the effects of alkalization may decrease the release of calcium from bone. However, veterinary renal diets may also enhance renal calcitriol synthesis caused by the dietary restriction of phosphorus. This increase in calcitriol synthesis could offset the advantage of the decreased calcium absorption in cats with IHC.

Veterinary diets developed to prevent calcium oxalate urolithiasis (e.g., Eukanuba/Iams Moderate pH/O, Hill's Science Diet X/D, Royal Canin/IVD Urinary SO, Purina Veterinary Diets UR Urinary St/Ox) may be beneficial in the treatment of cats with IHC. These diets are restricted in calcium and have less urinary acidification (neutral pH urine production). Some are also restricted in oxalic acid and sodium and have increased moisture in the canned formulation. In two of three cats with IHC and calcium oxalate uroliths, hypercalcemia resolved after feeding a calcium oxalate-prevention diet. One cat did not become normocalcemic but did have a reduction in the magnitude of hypercalcemia.

The addition of sodium chloride may be useful in cats with IHC as long as the added salt enhances calcium excretion without an increased risk of calcium oxalate uroliths. Increased dietary sodium chloride increases urine volume but does not increase calcium oxalate relative supersaturation in healthy cats. However, an increase in urinary excretion of calcium does not always correlate to the development of calcium urolithiasis, since the concentration of calcium in the urine also depends on the degree of water excreted at the same time. At this time the effects of additional dietary sodium chloride have not been examined in cats with IHC.

It is doubtful that IHC is the result of excess vitamin D intake since concentrations of 25-hydroxyvitamin D have been within the reference range in most cats with IHC. However, the minimal requirement for vitamin D in cats is debatable since reference ranges have been established in cats fed vitamin D-supplemented diets. Normal concentrations of 25-hydroxyvitamin D could still potentially be associated with IHC in cats if there are mutations in the vitamin D or calcitriol receptors. These possibilities have not yet been investigated. Since the amount of vitamin D supplied in most diets is not listed on the diet label, it is difficult to choose a diet that is lower in vitamin D.

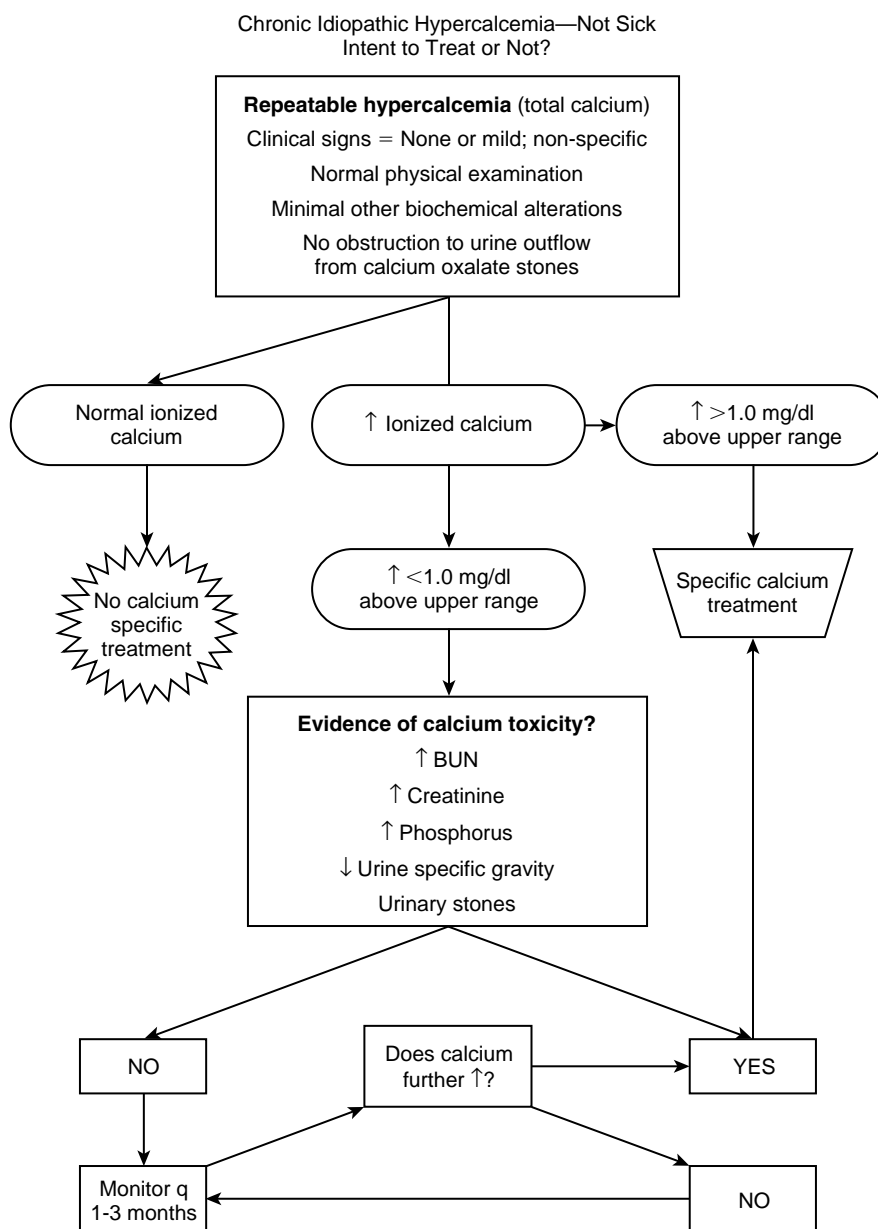

Fig. 52-1 Diagnostic plan for initiation of treatment in hypercalcemic cats.

Hypercalcemia may return in some cats with IHC that previously have been successfully treated with a dietary change. In these cases changing to another diet or medical therapy should be considered.

Glucocorticosteroids

If normocalcemia has not been restored after a dietary feeding trial of 6 to 8 weeks, treatment with glucocorticosteroids should be considered. Administration of glucocorticosteroids can decrease serum calcium concentration by decreased intestinal absorption of calcium, decreased renal tubular calcium resorption, and

decreased skeletal mobilization of calcium. Cats usually do not exhibit serious side effects from glucocorticosteroid treatment as do dogs. Prednisone is given orally at 5 mg/cat/day for 1 month before reevaluation. If iCa concentration is normal, this dose is continued for several months. If serum iCa concentration is still increased, the dose is increased to 10 mg/cat/day. Some cats may require as much as 15 to 20 mg of prednisone per day to restore normocalcemia. Approximately 50% of cats with IHC become normocalcemic with 5 or 10 mg of prednisone per day, but some may require increasing doses to remain normocalcemic over time.

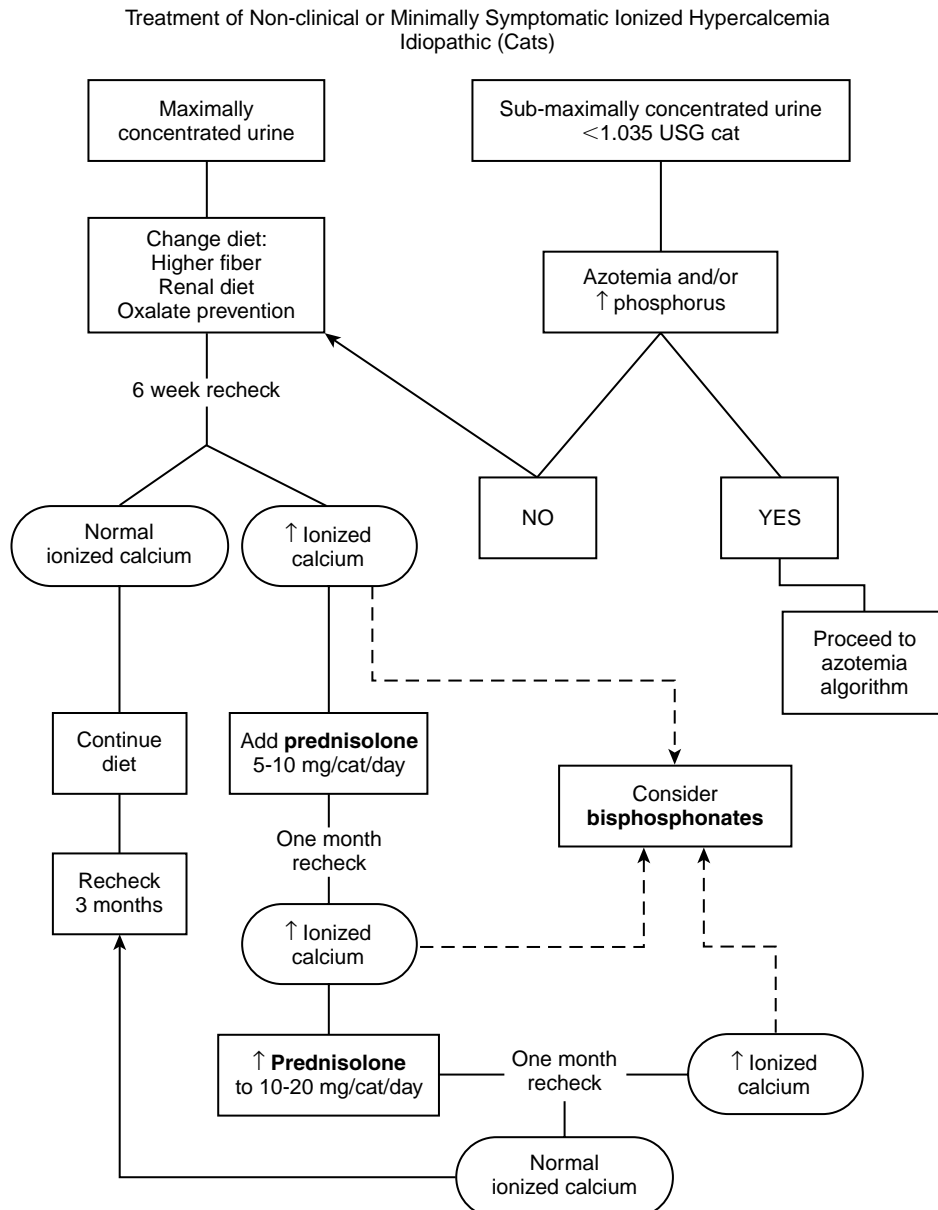

Fig. 52-2 Treatment of minimally symptomatic ionized hypercalcemia in cats.

There is some concern that glucocorticosteroids may increase urinary excretion of calcium, contributing to calcium oxalate urolith formation. However, little is known regarding the effects of glucocorticosteroids on filtration and tubular resorption of calcium in the cat. In a few healthy cats that have been studied, oral prednisolone treatment did not result in diuresis or an increase in calcium oxalate excretion.

Bisphosphonates

Bisphosphonates reduce the activity and number of osteoclasts following binding to hydroxyapatite. Treatment with bisphosphonates may be useful for hypercalcemia in IHC if there is increased osteoclastic bone resorption.

Bisphosphonate therapy may be an alternative to glucocorticosteroid use in cats that failed dietary intervention. The safety and efficacy of pamidronate given intravenously to two cats with hypercalcemia have been reported. Adequate hydration is essential when treating with bisphosphonates since these drugs may cause nephrotoxicity, especially at higher doses. A small number of cats with IHC have been treated successfully with 10 mg of alendronate orally once weekly for up to 1 year. Erosive esophagitis is noted as a possibility in women receiving oral bisphosphonates; although the risk for development of esophagitis in cats is unknown, it is recommended to follow the weekly pill with 6 ml of water given with a dosing syringe and then to dab a small amount of butter on the cat's lips to increase licking and salivation, which

Treatment of Cats with Idiopathic Hypercalcemia and Azotemia

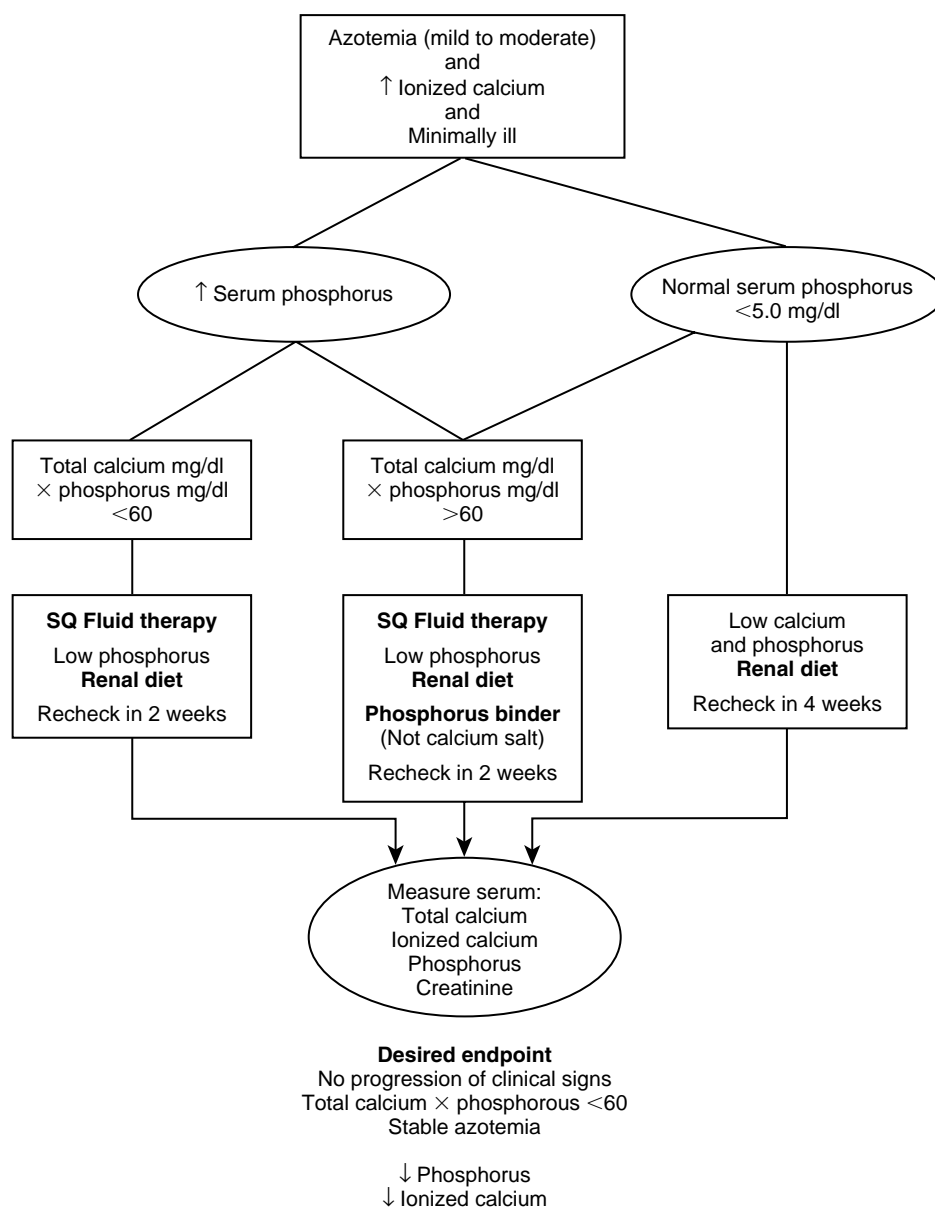

Fig. 52-3 Treatment plan for mild-to-moderate chronic ionized hypercalcemia.

further promotes the transit of the pill to the stomach. As seen with other therapies, hypercalcemia may return after a period of normocalcemia, requiring an increase in dose. Unfortunately the long-term safety and efficacy of oral bisphosphonates in cats is unknown.

Miscellaneous Treatments

Fluid therapy is a possible treatment option in cats with IHC but has not been evaluated. The administration of subcutaneous fluids on a daily or every-other-day basis potentially could expand the extracellular fluid and promote calciuresis. Diuretics such as furosemide have been used effectively to decrease serum iCa during acute rescue

protocols for hypercalcemia, usually in combination with intravenous fluids. Little is known about the effects of chronic furosemide administration regarding calcium status and the development of dehydration. It is a concern that cats receiving chronic diuretics will undergo diuresis but will not increase their water intake, leading to dehydration.

Calcimimetics are a new class of drug that has emerged in human medicine. Calcimimetics interact with the calcium receptor directly and have been proven effective in lowering iCa, phosphorus, and PTH concentrations in human dialysis patients. The potential future use of calcimimetics in the treatment of IHC is an interesting possibility.

CHAPTER 53

Treatment of Hypoparathyroidism

DENNIS J. CHEW, *Columbus, Ohio*
 LARRY A. NAGODE, *Columbus, Ohio*
 PATRICIA A. SCHENCK, *Lansing, Michigan*

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Hypoparathyroidism is a state of absolute or relative deficit of parathyroid hormone (PTH) secretion that can be permanent or transient. Hypocalcemia and clinical signs referable to low ionized calcium are the hallmarks of advanced hypoparathyroidism. This endocrine disorder is an uncommon cause of hypocalcemia in dogs and cats (Box 53-1), but it is the only condition requiring acute and chronic treatment to alleviate clinical signs associated with hypocalcemia. Hypoparathyroidism in dogs is most commonly an idiopathic or primary condition, whereas surgical removal or injury during thyroidectomy to correct hyperthyroidism is the most common cause in cats. In humans with idiopathic hypoparathyroidism, a variety of mutations have been identified that affect PTH production or PTH receptors (pseudohypoparathyroidism), but these conditions have not yet been described in dogs or cats. The treatment for hypoparathyroidism is the same, regardless of cause or genetic defect.

Inappropriately low levels of PTH cause hypocalcemia, hyperphosphatemia, and decreased levels of

1, 25-dihydroxycholecalciferol (calcitriol). Hypocalcemia is explained by increased urinary loss (hypercalciuria), reduced bone mobilization, and decreased intestinal absorption as a result of decreased calcitriol formation during periods of low PTH levels. Hyperphosphatemia results from the decreased urinary loss of phosphorus (hypophosphaturia), which overcomes decreased bone mobilization and low intestinal absorption of phosphorus during periods of decreased PTH levels. PTH is a potent stimulator, and phosphorus is a potent inhibitor of the 25(OH)-cholecalciferol-1 α -hydroxylase system in the renal tubules; consequently, the absence of PTH and the presence of hyperphosphatemia work together to decrease renal synthesis of calcitriol. Decreased levels of calcitriol contribute to hypocalcemia largely through decreased intestinal calcium absorption. A component of hypocalcemia that is unrelated to low PTH levels may arise from increased uptake of calcium into bone following rapid correction of long-standing hyperparathyroidism or hyperthyroidism, both of which are associated with loss of bone calcium before treatment (hungry bone syndrome).

Box 53-1

Conditions Associated With Hypocalcemia Based on Total Serum Calcium**Common**

- Hypoalbuminemia (ionized calcium is normal)
- Chronic renal failure
- Puerperal tetany (eclampsia)
- Acute renal failure
- Acute pancreatitis
- Undefined cause (mild hypocalcemia)

Occasional**Hypoparathyroidism**

- Primary
- Absent or destruction of parathyroid glands
- Idiopathic-spontaneous/immune
- Bilateral thyroidectomy
- Following sudden reversal of chronic hypercalcemia (atrophy of remaining parathyroid glands)
- Suppressed PTH secretion (without destruction of gland)
- Magnesium depletion or excess
- After sudden reversal of hypercalcemia
- Ethylene glycol intoxication
- Phosphate enema
- Following NaHCO_3 administration
- Soft-tissue trauma/rhabdomyolysis

Uncommon

- Laboratory error
- Improper sample anticoagulant (ethylenediaminetetraacetic acid)
- Rapid intravenous infusion of phosphates
- Acute calcium-free intravenous infusion (dilutional)
- Intestinal malabsorption/severe starvation
- Hypovitaminosis D
- Blood transfusion (citrate anticoagulant)
- Nutritional secondary hyperparathyroidism
- Infarction of parathyroid gland adenoma (dog)
- Hypomagnesemia
- Tumor lysis syndrome
- Canine distemper virus affecting parathyroid gland

Human

- Sepsis/critical illness
- Drug-induced hypoparathyroidism (aluminum, asparaginase, doxorubicin, cytosine arabinoside, cimetidine, ethanol)
- Antiresorptive agents (estrogen, plicamycin, calcitonin, bisphosphonates)
- Pseudohypoparathyroidism
- Parathyroid gland agenesis
- Osteoblastic bone neoplasia (prostate cancer)
- Hypercalcitonism
- ^{131}I radiation damage

Magnesium also plays a role in PTH production. Severe magnesium depletion blunts maximal PTH secretion, increases end-organ resistance to PTH, and may also impair calcitriol synthesis.

Veterinary patients with hypoparathyroidism can be divided into three categories: (1) those with absence or

destruction of parathyroid glands, (2) those with sudden correction of chronic hypercalcemia, or (3) those with suppressed secretion of or responsiveness to PTH without parathyroid gland destruction. The most common category of hypoparathyroidism in dogs and cats is that associated with the absence or destruction of the parathyroid glands.

CLINICAL SIGNS

Clinical signs related to hypocalcemia are identical, regardless of the underlying cause. Decreased serum ionized calcium concentration increases excitability of neuromuscular tissue, which accounts for many of the clinical signs of hypoparathyroidism. Mild decreases in serum ionized calcium may result in no obvious clinical signs. The duration and magnitude of the decrease in serum calcium, as well as the rate of decrease, interact to determine the severity of clinical signs. In its most severe forms, hypocalcemia can cause death from harmful circulatory effects (hypotension and decreased myocardial contractility) and respiratory arrest from paralysis of respiratory muscles. Serum total calcium concentration below 4 mg/dl can cause death especially if the decline was rapid. Other electrolyte and acid-base abnormalities can either magnify or diminish the signs of hypocalcemia. Correction of hypokalemia may precipitate the onset of clinical signs of hypocalcemia when hypocalcemia is present concurrently. Respiratory alkalosis following exercise or excitement may also increase the clinical signs of hypocalcemia as ionized calcium shifts to the protein-bound fraction.

Clinical signs of primary hypoparathyroidism from hypocalcemia include seizures, muscle tremors or fasciculations, muscle cramping, stiff gait, and behavioral changes (restlessness, excitation, aggression, hypersensitivity to stimuli, disorientation) (Box 53-2). Most seizures resolve without treatment but often recur despite treatment with anticonvulsants. Growling attributable to pain or behavior change and intense rubbing of the face with the paws or on the ground are commonly observed. These signs are attributed to either paresthesias or pain from facial muscle spasms. Pyrexia may be caused by increased muscular activity; lethargy, anorexia, and weakness may be noted, especially in cats. Polyuria and polydipsia occur in some cases as a result of psychogenic mechanisms or renal injury from hypercalciuria. Anterior and posterior lenticular cataracts occur in some affected dogs and cats, and prolapse of the third eyelid is sometimes seen with acute hypocalcemia in cats.

Seizures caused by hypocalcemia appear different than those associated with idiopathic epilepsy. With hypocalcemia, seizures are often preceded by apprehension or nervousness, and affected animals may remain partially conscious and retain urinary continence during the seizure. Clinical signs caused by acute postoperative hypocalcemia are similar in dogs and cats relating to excitation of neuromuscular tissue. Focal twitching of facial muscles and whiskers may be noticed before more generalized muscle tremors or seizures.

Box 53-2

Clinical Signs Associated With Severe Ionized Hypocalcemia**Common**

- Muscle tremors/fasciculations
- Seizures/status epilepticus
- Facial rubbing
- Muscle cramping
- Stiff gait
- Behavioral change
- Restlessness/excitation
- Aggression
- Hypersensitivity to stimuli
- Disorientation
- Growling

Occasional

- Panting
- Pyrexia
- Lethargy/depression
- Anorexia
- Prolapse of third eyelid (cats)
- Posterior lenticular cataracts
- Tachycardia/electrocardiogram arrhythmia, prolonged QT interval

Uncommon/None

- Polyuria/polydipsia
- Hypotension
- Respiratory arrest/death

DIAGNOSIS

There are numerous causes of hypocalcemia (see Box 53-1). However, primary hypoparathyroidism is the only disorder characterized by hypocalcemia, elevated serum phosphorus, and low PTH concentration, along with normal renal function. Decreased serum calcium with increased serum phosphorus may be seen in nutritional or renal secondary hyperparathyroidism, following phosphate-containing enema administration, and in tumor lysis syndrome; however PTH concentration is increased in all of these conditions. A presumptive diagnosis of hypoparathyroidism can be made on the basis of decreased serum calcium, high serum phosphorus, normal renal function, and the absence of an obvious alternative diagnosis. The definitive diagnosis of hypoparathyroidism requires the finding of an inappropriately low or reference range PTH level concurrently with hypocalcemia since hypocalcemia should provide a strong stimulus to the normal parathyroid gland to secrete PTH at a high level. Primary hypoparathyroidism requires lifelong treatment; thus confirmation of the diagnosis with PTH measurement is highly recommended. Since magnesium depletion can cause functional hypoparathyroidism, measurement of serum ionized magnesium concentration is also recommended since over 75% of dogs and cats with primary hypoparathyroidism have marginal or low serum ionized magnesium concentrations.

TREATMENT

Treatment is individualized based on the severity of calcium-specific signs, the magnitude of the hypocalcemia, the rapidity of the decline in serum calcium levels, and trends toward a further decrease or stability in the serum calcium concentration. More aggressive treatment is prescribed for patients with severe signs of hypocalcemia, patients with severe ionized hypocalcemia with or without signs, and patients in which the serum calcium level appears to be steadily or rapidly declining. Acute, subacute, and chronic rescue treatment regimens are available using supplementation with calcium salts and calcitriol (the active vitamin D metabolite). The goal of therapy is to predictably and smoothly increase the serum calcium concentration to a level that alleviates the signs of hypocalcemia, lessens the likelihood of hypercalcemia developing later, and reduces the magnitude of hypercalciuria. For suspected temporary postsurgical hypoparathyroidism, it is desirable to keep serum calcium levels on the low side to maximize compensatory hypertrophy of remaining parathyroid glands.

No treatment regimen completely compensates for the full physiologic actions of absent PTH. Calcitriol treatment corrects the low intestinal absorption of calcium but does not completely protect the kidneys from hypercalciuria as would occur when working in concert with PTH. Similarly, calcitriol does not exert as powerful an effect on bone in the absence of PTH. Replacement therapy with once-daily subcutaneous injections of human PTH-(1-34) is highly effective in humans and provides good 24-hour calcemic control with better control of serum phosphorus and less hypercalciuria. Use of synthetic human PTH amino terminal compounds for treatment of veterinary patients is conceivable but has not been used because of its cost and the rate of success of oral calcitriol and calcium supplementation.

Hypocalcemia that is severe enough to create clinical signs should be anticipated in dogs undergoing parathyroidectomy as treatment for hypercalcemia resulting from a parathyroid gland tumor (see chapter 54). Those with very high levels of serum calcium, PTH, and serum bone alkaline phosphatase (BALP) may be at greater risk for developing postoperative hypocalcemia. In these cases, postoperative hypocalcemia is the consequence of acute hypoparathyroidism from chronic suppression of the remaining parathyroid glands, as well as calcium uptake into "hungry bones." One should anticipate hypocalcemia in cats that undergo bilateral thyroidectomy since as many as 30% of patients can be expected to demonstrate a lower serum calcium level transiently.

We do not agree with the recommendation of others to wait for signs of tetany before instituting calcium-specific therapy to increase serum calcium. Preemptive therapy to increase serum calcium levels may be a good choice for patients with marked hypocalcemia despite an absence of clinical signs or for those in which calcium is steadily or rapidly declining. Prophylactic therapy to prevent hypocalcemia in dogs undergoing surgery for hyperparathyroidism should be considered, especially in those with more severe levels of hypercalcemia. Calcitriol should be started before surgery in these instances because there is

a lag until maximal effect; calcitriol given at the time of surgery or after surgery fails to prevent the development of hypocalcemia.

Acute Management of Hypocalcemia Causing Tetany or Seizures

Tetany or seizures caused by hypocalcemia requires treatment with intravenous calcium salts. Calcium is given to effect at 5 to 15 mg/kg of elemental calcium (0.5 to 1.5 ml/kg of 10% calcium gluconate) over a 10- to 20-minute period. The percentage of calcium varies widely with the specific calcium salt (Table 53-1). There is no difference in the effectiveness of intravenous calcium salts to correct hypocalcemia when the dose is based on elemental calcium content. Calcium gluconate is often chosen as the calcium salt of choice because it is nonirritating if the solution is injected outside a vessel; calcium chloride is extremely irritating to tissues but provides more elemental calcium in each milliliter of solution (see Table 53-1).

The heart rate and electrocardiogram should be monitored during acute infusion of calcium salts. Bradycardia may signal the onset of cardiotoxicity from infusing calcium at too rapid a rate; sudden elevation of the ST segment, shortening of the QT interval, or premature ventricular complexes may also indicate cardiotoxicity from the calcium infusion. Not all clinical signs immediately abate following acute correction of hypocalcemia because resolution of some signs may lag by as much as 30 to 60 minutes. Nervousness, panting, and behavioral changes may persist despite the return of normocalcemia during this period, perhaps reflecting a lag in cerebrospinal fluid equilibration with the calcium in extracellular water (since there is slow equilibration between calcium in extracellular water and that in cerebrospinal fluid). Hyperthermia that results from increased muscle tremor activity or seizures may also take some time to dissipate.

Subacute Management of Hypocalcemia

The initial bolus injection of elemental calcium can be expected to decrease signs of hypocalcemia for a limited time, for as little as 1 hour to as long as 12 hours if the initial cause of the hypocalcemia persists. Calcitriol therapy should be started as soon as possible because 24 hours to a few days of treatment are required before the effects to enhance intestinal calcium transport are maximized.

Additional parenteral calcium salt administration is necessary to maintain a required degree of calcemia until therapy with calcitriol is effective in maintaining serum calcium at acceptable levels.

Multiple intermittent intravenous injections of calcium salts can be given to control clinical signs, but this method is not recommended because wide fluctuations in serum calcium concentrations are likely to be encountered. Continuous intravenous infusion of calcium is recommended at 60 to 90 mg/kg/day of elemental calcium (2.5 to 3.75 mg/kg/hour) until oral medications provide calcemic control. Initial doses in the higher range are administered to patients with more severe hypocalcemia, and the dose is decreased according to the level of calcemia achieved. The dose of intravenous calcium is tapered further as oral calcium salts and calcitriol therapy become more effective.

Ten milliliters of 10% calcium gluconate provides 93 mg of elemental calcium. A convenient method to infuse calcium is available when intravenous fluids are given at a maintenance volume of 60 ml/kg/day (2.5 ml/kg/hour). Approximately 1 mg/kg/hour, 2 mg/kg/hour, or 3 mg/kg/hour of elemental calcium is provided by adding 10, 20, or 30 ml of 10% calcium gluconate, respectively, to each 250-ml fluid bag. Obviously the same rate of calcium infusion is provided by adding 20, 40, or 60 ml of 10% calcium gluconate to each 500-ml fluid bag to be infused at maintenance rates.

Calcium salts should not be added to fluid therapy preparations that contain lactate, acetate, bicarbonate, or phosphates because calcium salt precipitates can occur. Alkalinizing fluid therapy containing sodium bicarbonate decreases ionized calcium and may expose clinical signs of hypocalcemia in animals with borderline hypocalcemia; consequently they should not be used.

Subcutaneous administration of calcium gluconate has been regarded as safe for use in hypocalcemia when diluted to at least 1:1 by volume. However, there are reports of adverse reactions when subcutaneous calcium gluconate has been administered, resulting in calcinosis cutis, pyogranulomatous dermatitis, dermoepidermal separation, skin ulceration, and severe pyogranulomatous panniculitis. Most animals are euthanized because of the severity of the skin reaction. Because of the severity of adverse reactions that have recently been observed, the administration of subcutaneous fluids containing calcium gluconate is no longer recommended.

Table 53-1

Treatment of Hypocalcemia With Parenteral Calcium*

Drug	Preparation	Available Elemental Calcium	Dose	Comment
Calcium (Ca) gluconate	10% solution	9.3 mg of elemental Ca/ml	a. Slow IV to effect (0.5-1.5 ml/kg) b. 5-15 mg/kg/hr elemental Ca IV	Stop if bradycardia or shortened QT interval occurs Infusion to maintain normal Ca
Calcium chloride	10% solution	27.2 mg of elemental Ca/ml	5-15 mg/kg/hr IV	Extremely caustic perivascularly

IV, Intravenously.

*Do not mix calcium solution with bicarbonate containing fluids because precipitation may occur.

Table 53-2

Treatment of Hypocalcemia With Oral Calcium Salts*

Drug	% Elemental Calcium Available	Preparation	Dose (Elemental) (mg/kg/day)	Comment
Calcium carbonate	40 (tablet)	Many sizes	25-50	Most common calcium supplement May cause gastric irritation
Calcium chloride	27	Powder	25-50	
Calcium citrate	21	Many sizes	25-50	
Calcium lactate	13 (tablet)	325, 650 mg tablets	25-50	
Calcium gluconate	10	Many sizes	25-50	

*Oral calcium: Calculate dose on elemental calcium content.

Subacute and Chronic Maintenance Therapy

Supplemental elemental calcium is administered orally (Table 53-2) to guarantee adequate available calcium for intestinal absorption following activating effects from vitamin D metabolites. Oral calcium administered by pill or slurry is most important during initial treatment, especially if the animal is not eating. Active intestinal transport mechanisms of calcium uptake are under the control of calcitriol when calcium intake is low, but vitamin D-independent passive intestinal absorption of calcium occurs when calcium intake is high. One can take advantage of the passive mechanisms for intestinal calcium transport before vitamin D actions are effected in the intestine. Normal dietary intake contains sufficient calcium to maintain adequate calcium levels in the presence of vitamin D metabolite treatment for most patients. Consequently oral calcium salt supplementation can be tapered and discontinued in many instances as vitamin D compounds reach maximal effect.

Calcium carbonate is the most widely used oral preparation of the commonly prescribed calcium salts because it contains the greatest percentage of elemental calcium, and this translates into fewer pills administered. The degree of calcium ionization and bioavailability for absorption vary by the specific calcium salt and the conditions within the intestine; consequently it is not simply a matter of determining the elemental calcium content of a specific oral calcium salt. Oral calcium is usually given at 25 to 50 mg/kg/day of elemental calcium divided over the day. Oral calcium carbonate serves as an intestinal phosphate binder in addition to providing additional calcium for intestinal absorption. It is advisable to continue

oral calcium carbonate therapy for its intestinal phosphate-binding effects if serum phosphorus levels remain increased. Lower serum phosphorus concentrations may allow increased endogenous synthesis of calcitriol as the phosphate-mediated inhibition of the renal tubular 1α -hydroxylase system in the renal tubules is relieved.

Vitamin D preparations (Table 53-3) include ergocalciferol, cholecalciferol, 25(OH)-cholecalciferol (calcidiol), 1α -hydroxycholecalciferol, and 1,25-dihydroxycholecalciferol (calcitriol). Ergocalciferol and calcitriol are the preparations most commonly used in veterinary medicine. Dihydroxycholecalciferol (DHT) has been used in the past but is no longer available. Lifelong treatment with some form of vitamin D metabolite is necessary for patients with primary hypoparathyroidism or in those with postoperative hypocalcemia that fails to resolve.

Ergocalciferol is favored by some because of its low cost, but it has several features that make it the least attractive agent for treatment. Ergocalciferol and its immediate metabolite 25-hydroxyergocalciferol have minimal vitamin D receptor avidity; consequently high doses are used to increase interactions with the vitamin D receptor. Calcitriol is about 1000 times as effective as the parent vitamin D compound and 500 times as effective as its precursor calcidiol (25-hydroxyvitamin D) in binding to the natural calcitriol receptor. Ergocalciferol is highly lipid soluble, requiring weeks to saturate body stores to achieve maximal effect; it also has a long half-life. Consequently prolonged periods of hypercalcemia occur after any overdose with ergocalciferol. In addition, there is extreme individual variation in the dose of ergocalciferol required to achieve the target level of serum calcium. Loading doses reduce the time required to achieve maximal calcemic effect (see Table 53-1).

Table 53-3

Vitamin D Compounds

Preparation	Daily Dose	Time for Maximal Effect To occur	Time for Toxicity Effect To Resolve
Vitamin D ₂ (ergocalciferol)	Initial: 4000-6000 U/kg/day Maintenance: 1000-2000 U/kg once daily to once weekly	5-21 days	1-18 weeks
1,25-Dihydroxyvitamin D ₃ (Calcitriol)	Initial: 20-30 ng/kg/day \times 3-4 days Maintenance: 5-15 ng/kg/day	1-4 days	2-7 days

Calcitriol is the vitamin D metabolite of choice to provide calcemic actions because it has the most rapid onset to maximal action and the shortest biologic half-life. The dose of calcitriol can be adjusted more frequently because of more “real-time” effects on serum calcium. Should hypercalcemia occur, it is likely to abate quickly following dose reduction. The half-life of calcitriol in blood is 4 to 6 hours, whereas its biologic half-life is 2 to 4 days, which facilitates the rapid correction of hypercalcemia should it occur. A loading protocol for calcitriol use is used when more rapid calcium correction is desirable. A loading dose of calcitriol of 20 to 30 ng/kg/day for the initial 3 to 4 days, followed by a maintenance dosage of 5 to 15 ng/kg/day, is effective in most patients. Calcitriol only programs undifferentiated cells in the intestinal crypts of Lieberkühn, and the turnover of crypt cells is complete every 24 hours. For this reason the dose of calcitriol is divided twice daily to ensure sustained priming effects on intestinal epithelium for calcium transport. Calcitriol is available commercially in 0.25- and 0.50-mcg capsules (250 and 500 ng per respective capsule; Rocaltrol, Hoffman-LaRoche) and in a liquid form at 1 mcg/ml (1000 ng/ml). Reformulation of calcitriol capsules in doses suitable for a variety of animal sizes is necessary. It may be useful to prescribe calcitriol in liquid formulation so that small adjustments in dosage can be made accurately. A number of specialty pharmacies reformulate human drugs for veterinary use and can create any calcitriol doses needed. If there is documented low serum ionized magnesium concentration, supplementation with magnesium should also be considered (magnesium sulfate, 1 to 2 mEq/kg/day). In some cases correction of serum ionized magnesium deficiency may lead to a decrease in required doses of calcium and calcitriol.

Thiazide diuretics are sometimes used to treat humans with primary hypoparathyroidism as a maneuver to reduce hypercalciuria. This is especially useful when hypercalciuria continues despite a serum calcium level that is within the low normal range. It is likely that further reduction of the calcitriol dose would be necessary after starting thiazides since calcium levels would be higher because of more reclaimed calcium by the kidney. The effects of thiazide diuretics on urinary calcium excretion are debatable in dogs and unknown in cats.

Following the Patient and Managing Complications

Periods of hypocalcemia and hypercalcemia occur sporadically in patients during initial efforts to manage serum calcium levels. Daily measurement of total serum calcium during the initial stabilization of serum calcium is necessary; then weekly calcium measurements suffice during maintenance therapy until the target level of calcium has been achieved and maintained. Quarterly measurement of total serum calcium is recommended thereafter in animals with permanent hypoparathyroidism. The target level for serum calcium ideally should be just below the reference range rather than the middle or upper range of normal calcium concentrations. This not only lessens the likelihood that hypercalcemia will develop but also reduces the level of hypercalciuria

that occurs in patients missing the renal effects of PTH. Maintaining a mildly decreased level of serum calcium also ensures an ongoing stimulus for hypertrophy of any remaining parathyroid tissue in patients with postoperative hypoparathyroidism.

It is important to change the dose of calcitriol gradually following evaluation of serum calcium values and to make sure that enough time has elapsed to observe its maximal effect before the dose is changed. The time lag for this effect varies with the vitamin D metabolite used (see Table 53-1). Dosage increases of 10% to 20% are recommended for most cases that are still below the desired calcium target level. Vitamin D metabolites and calcium salt supplementation should be discontinued temporarily in patients with hypercalcemia. Doses should be reduced until the serum calcium level falls to just less than the reference range.

Hypercalcemia is a serious side effect that can result in the death of the animal or chronic renal damage severe enough to cause both acute and chronic renal failure. Owners should be taught the early signs of hypercalcemia and instructed to seek veterinary attention so that serum calcium can be measured if signs suggest hypercalcemia. Signs of hypercalcemia that clients are likely to recognize include polydipsia and polyuria, anorexia, vomiting, and depression. Animals with severe hypercalcemia require a combination of hospitalization, intravenous fluids, furosemide, steroids, and perhaps bisphosphonates or calcitonin initially. All patients with symptomatic vitamin D metabolite-induced hypercalcemia should be placed on a calcium-restricted diet because hypervitaminosis D is a form of hypercalcemia in which intestinal hyperabsorption of calcium contributes substantially to the development of hypercalcemia.

The long-term prognosis for quality and length of life has not been reported for dogs and cats during treatment of chronic hypoparathyroidism. Patients that have frequent episodes or long duration of hypercalcemia during treatment have poor prognoses. Patients that maintain calcium levels in the target zone are often managed successfully for years. In our experience patient management with calcitriol is easier and more successful in inducing and maintaining target zone calcium levels than are older therapeutic approaches.

Hypercalciuria, nephrocalcinosis, urolithiasis, and reduced renal function have all been noted in humans treated for chronic hypoparathyroidism. As many as 80% of humans treated for 2 years or longer have decreased creatinine clearance. These abnormalities can be attributed to episodes of hypercalcemia and hyperphosphatemia, as well as hypercalciuria that occurs in the absence of the full calcium-retaining actions of PTH at the level of the renal tubule. In the absence of PTH, hypercalciuria occurs more readily at all levels of serum calcium concentration and is especially severe as calcium concentrations approach the normal level, which increases the filtered load of calcium. Nephrocalcinosis, reduced renal function, and chronic renal failure have also been suspected in veterinary patients receiving long-term treatment for hypoparathyroidism, but the risk for these disorders has not been critically evaluated.

Great care is given to tailor the dosage of vitamin D metabolites in humans to both the level of serum calcium and the degree of hypercalciuria achieved during treatment. Maintaining a mildly decreased serum calcium level does not guarantee that hypercalciuria will not occur. Hypercalciuria is monitored by measuring 24-hour millimolar urinary calcium excretion or by determination of the urinary calcium:urinary creatinine ratio. Guidelines to assess the magnitude of hypercalciuria in veterinary patients have not yet been developed.

Calcitriol treatment is gradually tapered and then discontinued in patients with postsurgical hypoparathyroidism because hypocalcemia is usually transient. Most cats are able to maintain normal levels of serum calcium 2 weeks after thyroidectomy, although some may take as long as 3 months. Dogs with hypocalcemia usually require 6 to 12 weeks of treatment following removal of a parathyroid gland tumor. We usually start tapering calcitriol 1 month into therapy. If serum calcium declines substantially, the previous dose is resumed, and a taper attempted once again 1 or 2 months later. Permanent hypoparathyroidism is likely if failure to maintain reasonable levels of serum calcium occur following a taper of calcitriol at 3 months.

CHAPTER 54

Canine Hypercalcemia and Primary Hyperparathyroidism

EDWARD C. FELDMAN, *Davis, California*

RICHARD W. NELSON, *Davis, California*

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC APPROACH TO HYPERCALCEMIA

Hypercalcemia is an abnormality that is usually serendipitously identified on serum biochemical analysis. Disorders associated with hypercalcemia in dogs, in an approximate incidence order as seen at our hospital, include lymphosarcoma, acute and chronic renal failure, hypoadrenocorticism, primary hyperparathyroidism (PHP), vitamin D toxicosis, apocrine gland carcinoma of the anal sac, multiple myeloma, uncommonly in association with a variety of carcinomas (lung, mammary, nasal, pancreas, thymus, thyroid, vaginal, and testicular), and uncommonly in association with certain granulomatous

diseases (blastomycosis, histoplasmosis, schistosomiasis). Information from the history, physical examination, complete blood count (CBC), urinalysis, serum biochemistry analysis, thoracic and abdominal radiographs, abdominal ultrasound, and examination of cytology and biopsy specimens usually provide adequate information to establish the diagnosis in dogs.

History and Physical Examination

Since hypercalcemia is almost always an unsuspected finding, it is never a mistake to obtain a second blood sample to be certain that laboratory error has been ruled out. In our experience laboratory error is extremely rare. With

confirmation of hypercalcemia, the veterinarian should review the signalment and history with the owner to identify clues to a definitive diagnosis that may not have been noted initially. From the history one can attempt to identify a tentative explanation for the hypercalcemia such as possible exposure to toxins containing vitamin D (e.g., rodenticides, inappropriate supplementation of food), evidence of pain from a lytic bone lesion (multiple myeloma or mammary tumor), difficulty eating because of oral lesions associated with renal failure, or a waxing/waning course of illness sometimes noted with hypoadrenocorticism. The physical examination should also be repeated in an attempt to identify a tentative explanation for hypercalcemia. The spine, ribs, and long bones should be palpated to identify bone pain caused by a lytic lesion, the mammary chain evaluated for neoplasia, the oral cavity for "rubber jaw" or lesions consistent with renal failure, the rectal and perineal area for apocrine gland carcinoma of the anal sac or other tumor, the heart rate and pulse for abnormalities consistent with hypoadrenocorticism, and the peripheral lymph nodes for enlargement suggestive of lymphoma (most hypercalcemic lymphoma dogs have a mediastinal mass and unremarkable peripheral nodes). Dogs with PHP have unremarkable physical examinations, and parathyroid masses are rarely palpable.

Routine Database

A thorough review of the CBC, serum biochemistry profile, and urinalysis should be completed. The urine specific gravity is commonly less than 1.020 in hypercalcemic dogs with renal disease, hypoadrenocorticism, and primary hyperparathyroidism. Urinary tract infection is common in these disorders. The CBC may demonstrate a normocytic, normochromic, nonregenerative anemia that is relatively common in renal failure, hypoadrenocorticism, and various neoplasias. The serum biochemistry profile should also be reviewed to assess the blood urea nitrogen (BUN), creatinine, and serum phosphate for increases consistent with renal failure; hyperkalemia and hyponatremia consistent with hypoadrenocorticism; hyperglobulinemia consistent with myeloma; and abnormal liver enzyme activities in association with a variety of malignancies. To this point the only "new" expense has been the repeated serum calcium concentration since all we have done is talk with the owner, repeat a physical examination, and review the laboratory results that were already obtained to identify the hypercalcemia in the first place.

Radiographs and Ultrasonography

Assuming that the review of the history, physical examination, and database has not defined the cause for hypercalcemia, thoracic radiographs are the next diagnostic step. The primary purpose for this study is to assess the cranial mediastinum for a mass consistent with lymphoma. If present, fine-needle aspiration or tissue obtained via biopsy should be evaluated. Radiographs also provide an opportunity to evaluate the perihilar

area and lungs for neoplasia or systemic mycoses, the spine and ribs for lytic lesions caused by neoplasia, and the heart for microcardia of hypoadrenocorticism. Abdominal radiographs can also be assessed, although ultrasound examination of the abdomen is preferred. The size and consistency of the liver, spleen, and mesenteric and sublumbar lymph nodes can be evaluated for abnormalities suggestive of malignancy (lymphoma) or other conditions. Diagnostic imaging to evaluate for malignancy (lymphoma) applies to a variety of tumors located in other organs, but tumors other than lymphoma are an uncommon cause of hypercalcemia. When possible, abnormal areas should be aspirated or biopsied to determine the presence or absence of neoplasia. The size and consistency of the kidneys can be assessed, although renal failure should have been ruled in or out on the initial blood test results. The bladder should be evaluated for the presence of cystic calculi, which develop in about 30% of dogs with PHP and can develop in any hypercalcemic dog. If these studies fail to indicate a diagnosis other than PHP, the index of suspicion for PHP increases. Until a specific cause for hypercalcemia is confirmed, lymphoma should never be ruled out. Cervical ultrasonography, which is discussed in a later section, has become an extremely valuable screening test in dogs with hypercalcemia.

SIGNALMENT, HISTORY, AND PHYSICAL EXAMINATION IN DOGS WITH PRIMARY HYPERPARATHYROIDISM

Dogs with PHP are usually 6 years of age or older. The mean age from our series of 210 dogs with PHP was 11.2 years. Dogs of both genders are almost equally affected, and about 20% of affected dogs are keeshonds. Dogs with PHP, unlike those afflicted with most other diseases that cause hypercalcemia, are usually not ill or not as ill. Owners of 88 of 210 PHP dogs had observed no abnormalities in their pet related to hypercalcemia. The reason that blood had been obtained from these dogs was as part of a routine geriatric evaluation or as part of a preanesthesia screen before a dentistry procedure.

The most common owner-observed abnormalities in dogs with PHP (~50%) were those suggestive of urolithiasis or urinary tract infection (i.e., straining to urinate, increased frequency of urination, and hematuria), both relatively common in PHP. Other clinical signs reported by owners of 210 dogs with PHP included polyuria and polydipsia (48% of dogs), weakness (46%), decreased activity (43%), decreased appetite (37%), weight loss or muscle wasting (18%), vomiting (13%), and shivering or trembling (10%). It is important to remember that, even when clinical signs are observed, they are often relatively mild. When observed, signs were present for as long as 2 years. Few abnormalities are detected on physical examination. In 149 of 210 dogs with PHP (71%), the medical record stated that no abnormalities were noted on physical examination. When noted, abnormalities included muscle wasting, slow to rise, obesity in some, and thin body condition in others. Each of these problems was seen in less than 10% of dogs with PHP.

CLINICOPATHOLOGIC ABNORMALITIES IN DOGS WITH PHP

Hypercalcemia (i.e., serum total calcium concentrations greater than 12 mg/dl; reference range of 9.9 to 11.6 mg/dl) was identified in all 210 dogs. This degree of “sensitivity” (100%) may be slightly misleading since we do not evaluate dogs for hypercalcemia unless this criterion is met. The mean total serum calcium concentration was 14.5 mg/dl with a range of 12.1 to 23.4 mg/dl. About 50% of these dogs had serum total calcium concentrations greater than 12 and less than 14 mg/dl; about 30% had values greater than 14 and less than 16 mg/dl, about 10% had values greater than 16 and less than 18 mg/dl, and slightly more than 5% had values greater than 18 mg/dl. The mean plasma ionized calcium concentration in the 210 dogs with PHP was 1.71 mmol/L (range 1.22 to 2.41; normal reference range 1.12 to 1.41 mmol/L). Just under 10% of the dogs with PHP had a serum ionized calcium concentration within the reference range, almost 30% had values between 1.42 and 1.65 mmol/L, and almost 50% had concentrations between 1.66 and 1.90 mmol/L, with the remaining 16% having concentrations greater than 1.91 mmol/L.

It may be of interest to point out the most common reason for *referral* of dogs ultimately diagnosed with PHP: concern on the part of the referring veterinarian that, if not treated, these dogs would develop renal failure. However, this is not the case. Of 210 dogs with PHP, their mean BUN concentration (<17 mg/dl) was less than the reference range of 18 to 30 mg/dl; their mean serum creatinine concentration (0.8 mg/dl) was well within the reference range; and their mean serum phosphate concentration (2.8 mg/dl) was less than the reference range of 3 to 6.5 mg/dl. All of these values were significantly less than values from 200 dogs of similar ages that were randomly reviewed from our hospital population. In other words, PHP actually seems to protect these dogs from renal failure rather than predisposing to this condition. Duration of hypercalcemia also was not a factor since some PHP dogs went as long as 2 to 3 years without treatment. The polyuria and polydipsia were well supported by finding a mean urine specific gravity of 1.012 in 210 dogs with PHP. Of the dogs with PHP, 30% had urinary tract infection, and about 30% had cystic calculi. Although impending renal failure is rare and not a reason for treating a dog that has PHP, infection and calculi are common and certainly would be reason for recommending therapy.

CONFIRMATION OF PRIMARY HYPERPARATHYROIDISM (Use of Serum Parathyroid Hormone and Parathyroid Hormone-Related Protein Concentrations)

Are Parathyroid Hormone Assay Results Vital?

Veterinarians value a logical, practical, and cost-effective approach to problem solving. One can rest assured that

the differential diagnosis for hypercalcemia is relatively small and veterinarians should be able to rule in or rule out most of the possibilities based on the diagnostic approach recommended at the beginning of this chapter. The need for sophisticated and relatively expensive studies such as assaying serum parathyroid hormone (PTH) and parathyroid hormone-related protein (PTHrP) concentrations take on less importance in this context. We have assayed serum PTH concentrations on every dog with PHP that we have diagnosed since the early 1980s. However, to be fair, a majority of these results are seen days to weeks *after* treatment has been completed. In other words, diagnosis was made without evaluating these assay results because a logical approach to the potential causes of hypercalcemia was used. This is not to suggest that the assays have no value; rather it is to suggest that in many dogs the assay results are not vital.

Serum Parathyroid Hormone Concentrations

Serum PTH concentrations are commercially available, and normal-to-increased concentrations confirm the diagnosis of PHP in nonrenal failure hypercalcemic dogs. Dogs with renal failure may also have increased serum PTH concentrations; therefore, within the context of the renal parameters, the serum phosphate concentration, the ionized serum calcium concentration, and other pertinent information, PHP should be distinguished from renal failure.

One must remember that, as serum calcium concentrations rise in healthy dogs, serum PTH concentrations should become undetectable. Therefore the term *normal range* can be misleading since the average dog with PHP has a serum PTH concentration that is “normal.” This seems counterintuitive. The term *reference range* makes more sense since increasing serum calcium concentrations should drop the serum PTH concentration below the reference range, whereas values within the reference range are physiologically abnormal when an individual is hypercalcemic. The reference range for serum PTH concentrations is 2 to 13 pmol/L, and 135 of 185 (73%) dogs with PHP had serum PTH concentrations within that range: 45% had results of 2.3 to 7.9 pmol/L, 28% had results of 8 to 13 pmol/L, 11% had results between 13 and 20 pmol/L, and 16% had results >20 pmol/L.

Serum Parathyroid Hormone-Related Protein Concentrations

Increased serum PTHrP concentrations in hypercalcemic dogs would be most consistent with lymphoma or apocrine gland carcinoma of the anal sac. If a specific explanation for hypercalcemia remains elusive, we recommend that “response to treatment” be a *last resort*. Before any medication is given, aspiration or biopsy of lymph nodes, spleen, and/or liver should be considered in an attempt to rule out lymphoma. Lymphoma is emphasized here because in some dogs it can be quite difficult to confirm, even more difficult if glucocorticoids have been administered.

LOCALIZING PARATHYROID TISSUE CAUSING HYPERPARATHYROIDISM

Surgery

Once the diagnosis of PHP has been confirmed, the most cost-effective and expedient approach to patient management is surgical exploration of the neck. Abnormal, autonomously secreting parathyroid masses may not always be obvious at surgery, although experienced surgeons rarely have difficulty in identifying the parathyroid tissue causing hypercalcemia. The abnormal parathyroid adenoma, carcinoma, or adenomatous hyperplastic tissue is typically larger and a different color than normal parathyroid glands. Surgeons may benefit from knowing which side of the neck or specific location within one side of the neck that a tumor or abnormal parathyroid tissue is likely to be found.

Cervical Ultrasound

Ultrasound examination of the cervical area has recently received attention because it is available, noninvasive, and relatively cost efficient. Ultrasonography, as much as any diagnostic tool used in veterinary medicine, is "operator dependent." The skill of the individual performing the examination is a major factor in assessing the value of ultrasound. As facilities, use of various transducers, and the experience of radiologists and internists improve, this diagnostic tool holds great potential. Parathyroid tumors are typically round-to-oval hypoechoic masses that measure 4 to 8 mm in greatest diameter. Some are as large as 20 mm in greatest diameter. Most masses are 4 to 6 mm in greatest diameter. Cervical ultrasound was performed in 130 of 210 dogs with PHP in our series. In 116 of these 130 dogs, a solitary parathyroid mass was visualized. In 13 dogs two distinct parathyroid masses were seen. In one dog no parathyroid mass was visualized. Ultrasonography correctly identified 142 of 143 parathyroid tumors. This level of success is impressive, but it is a direct reflection of the experience of the individuals performing the ultrasound examinations and the quality of the imaging equipment used. Less experienced radiologists or internists may not visualize a parathyroid mass that a more experienced person would identify and ultrasound systems and transducers with insufficient imaging resolution may also lead to false negative or positive diagnoses.

Other Tests

Abnormal parathyroid tissue has been localized in humans using technetium 99 sestamibi nuclear scintigraphy. Results in dogs with PHP have been inconsistent at best, and the procedure is not recommended. Recent attempts to localize abnormal parathyroid tissue using selective venous sampling to measure the serum concentrations of PTH have not been satisfactory.

TREATMENT OF PRIMARY HYPERPARATHYROIDISM

Pretreatment Considerations—Candidates for Percutaneous Treatment

Treatment options for PHP include surgical removal and percutaneous heat or ethanol ablation. Several factors

should be considered before suggesting a treatment recommendation. First, if a dog has cystic calculi, especially a male dog, surgery is recommended to remove the calculi; surgery on the neck to remove the parathyroid tumor is performed under the same anesthesia. Second, percutaneous treatment candidates must have a tumor large enough to have a needle placed percutaneously, and the mass cannot be too close to the carotid artery. Masses larger than 15 mm in greatest diameter are uncommon and often are managed surgically since we do not have much experience percutaneously ablating masses this large. If a dog has two parathyroid masses and one is located on each side of the neck, surgery is recommended; alternatively the percutaneous treatment can be "staged" at least 30 days apart to avoid iatrogenic laryngeal paralysis, an uncommon but possible problem.

Pretreatment Considerations—Serum Calcium Concentrations

If the pretreatment serum calcium concentration is ≥ 12 but ≤ 14 or fewer mg/dl, we simply monitor serum calcium or ionized calcium concentrations twice daily for 5 to 7 days after surgery or percutaneous therapy. Typically dogs are not at risk for developing hypocalcemia in the first 24 to 48 hours after treatment. Vitamin D therapy is only instituted if the serum calcium concentration decreases below 8 mg/dl, the ionized calcium decreases below 0.85 mmol/L, or clinical signs of tetany are observed. This level of decrease usually takes 3 to 7 days. If the serum calcium concentration before therapy is ≥ 15 mg/dl or if a dog has more than one parathyroid mass, the incidence of postsurgical hypocalcemia is greater, and we initiate vitamin D therapy (calcitriol; 2 to 10 ng/kg BID) the morning of or immediately after treatment. Vitamin D is then tapered to ever-decreasing dosages over a 2- to 6-month time period. Monitoring of serum calcium is carried forth as described, and parenteral calcium is only administered if tetany occurs or is thought to be imminent.

Percutaneous Ultrasound-Guided Heat Ablation

This procedure has become the recommended treatment of dogs with PHP at our hospital if the previously mentioned criteria are met. Dogs are placed under anesthesia, and with ultrasound guidance a needle is placed into the parathyroid mass. The needle is attached to a radio-frequency unit (radio frequency waves are naturally converted to heat at the needle tip). The wattage is started at a low level and increased based on observation of a "bubbling" appearance to the tissue. The needle tip is repositioned several times to ensure that the entire parathyroid mass has been ablated. Percutaneous ultrasound-guided heat ablation requires 15 to 30 minutes of anesthesia and is usually about one half the cost of surgery. Post-heat ablation management of the dog is identical to the management following surgical removal of a parathyroid mass. Of the first 48 dogs so treated, 44 (92%) had resolution of their PHP: 43 with one treatment, and one dog required a second procedure.

Percutaneous Ultrasound-Guided Ethanol Ablation

Percutaneous ethanol ablation is no longer recommended. The procedure used was similar to that described for the heat ablation except that the needle is connected to a syringe containing a volume of ethanol similar to the calculated volume of the parathyroid nodule. Ethanol was infused slowly in an effort to expose all tissue to ethanol, and the needle tip was repositioned several times to aid in accomplishing this goal. The reason that ethanol was abandoned was that leakage of this caustic material invariably occurred following the procedure. Such leakage could cause nerve damage and secondary laryngeal paralysis.

Surgery

Complete exploratory surgery of both thyroid lobe areas is recommended for dogs with PHP that do not meet the criteria for percutaneous ultrasound-guided heat ablation. An effort should be made to evaluate both sides of the neck and both the ventral and dorsal surfaces of the thyroid lobes. In most dogs with PHP the abnormal parathyroid tissue is solitary, off-color, and larger-than-normal; easily recognized; and easily extirpated. Only the abnormal parathyroid tissue is removed if possible; although, when a parathyroid tumor lies within a thyroid lobe, both are usually removed. If no parathyroid mass is observed and the diagnosis is thought to be correct, one thyroid/parathyroid complex should be removed and examined histologically. If two abnormal parathyroids are observed, both should be removed.

Since we began performing percutaneous treatment, 52 dogs have been treated at our hospital with surgery. Fifty of these 52 dogs (96%) had complete resolution of their PHP. One of these 52 dogs required a second procedure. Thus percutaneous and surgical treatments are both efficacious.

POSTTREATMENT CARE

Dogs are kept in the hospital for 5 to 7 days after treatment to monitor serum calcium concentrations and, more important, to keep the dog quiet. Since most dogs are quiet in the hospital, it can be appreciated that the quiet hypocalcemic dog is less prone to clinical tetany than would be the case if the dog is active. For this reason, dogs that are unusually active in the hospital are sent home. We usually monitor serum total calcium concentrations twice daily until release from the hospital.

Histology

Parathyroid tumors have been classified histologically as adenoma, carcinoma, or hyperplasia. These classifications have not had use clinically since all parathyroid masses are biologically similar. We have not experienced a dog with local tumor invasion or distant metastasis. Recurrence rate is about 10% regardless of the histology.

Immunosuppressive Agents

CLARE R. GREGORY, *Davis, California*

Over the last half of the 20th century immunosuppressive agents have evolved from nonspecific, myelotoxic drugs to agents that target specific enzymes catalyzing reactions required for normal immune function. Much of our current understanding of T-cell function has been provided by research performed to understand the mechanism of action of cyclosporine. As each element of antigen recognition, T-cell activation, cytokine synthesis, and T cell-dependent cytotoxicity is unraveled, investigators are devising specific, less toxic, and more efficacious agents for interrupting the immune response. This process, termed *rational drug development*, replaces the selection of potential immunosuppressive agents based on their ability to lyse or inhibit the activation of T and B cells in vitro. Although specific immunosuppression with the use of naturally induced and genetically engineered antibodies, soluble receptor fragments, and other biologic methods is available for the treatment of human diseases, most of these therapies are either inapplicable or unavailable for treatment of animal diseases. For the foreseeable future in veterinary medicine, immunosuppression will rely on chemotherapies. As new immunosuppressive agents become more available and clinicians familiar with their indications, effects, and adverse effects, immunosuppressive therapy should become more specific, effective, and safe.

MYELOTOTOXIC AGENTS

Cyclophosphamide

The major effect of cyclophosphamide results from alkylation of deoxyribonucleic acid (DNA) during the S phase of the cell cycle. The alterations in DNA structure can be lethal to the cell or may produce miscoding errors that inhibit cell replication or DNA transcription. Cyclophosphamide produces T- and B-cell lymphopenia and suppresses both T-cell activity and antibody production. Cyclophosphamide is administered to dogs for the treatment of corticosteroid-resistant immune-mediated hemolytic anemia (IMHA), corticosteroid-resistant immune-mediated thrombocytopenia (ITP), rheumatoid arthritis (RA), and polymyositis (in conjunction with corticosteroids). Cyclophosphamide is administered to cats for the treatment of IMHA and RA. Myelosuppression, gastroenteritis, alopecia, and hemorrhagic cystitis are the major complications associated with cyclophosphamide therapy.

Azathioprine

Azathioprine is a purine analog that is metabolized to ribonucleotide monophosphates. Poor conversion to

diphosphates and triphosphates leads to an intracellular accumulation of monophosphates that produces a feedback inhibition of the enzymes required for the biosynthesis of purine nucleotides. The triphosphate analogs that do form become incorporated into DNA and result in ribonucleic acid miscoding and faulty transcription. Azathioprine has a greater effect on humoral than on cell-mediated immunity. For the treatment of immune-mediated diseases in dogs, azathioprine is generally administered in conjunction with a corticosteroid and/or cyclophosphamide.

Azathioprine has been used for the treatment of IMHA, IMHA, autoimmune skin diseases, chronic hepatitis, myasthenia gravis, immune-mediated glomerulopathy, chronic atrophic gastritis, systemic lupus erythematosus, and inflammatory bowel disease. Although very myelotoxic in cats, azathioprine has been used for the treatment of feline autoimmune skin diseases. Azathioprine and prednisolone, when administered at maximally tolerated levels, do not effectively suppress the rejection response against canine major histocompatibility complex (MHC)-nonmatched renal allografts. However, when administered on an every-other-day schedule (1 to 3 mg/kg orally [PO]) with cyclosporine, azathioprine has been used to successfully maintain canine MHC-matched renal allografts. In feline renal transplantation patients with suspected inflammatory bowel disease or following an allograft rejection episode, azathioprine is administered with cyclosporine at a dose of 0.3 mg/kg every 3 days PO. The dose is decreased if the total white blood cell count falls below 3000 cells/ μ l or there is biochemical evidence of hepatotoxicity. The primary complication encountered with the administration of azathioprine is bone marrow suppression that can result in leukopenia, anemia, and thrombocytopenia. Acute pancreatitis and hepatotoxicity may also occur.

Methotrexate

Methotrexate competitively inhibits folic acid reductase, which is necessary for the reduction of dihydrofolate to tetrahydrofolate and affects the production of both purines and pyrimidines. The effects of methotrexate manifest during the S phase of the cell cycle. Methotrexate is used occasionally as an antineoplastic agent in dogs and cats for lymphomas, carcinomas, and sarcomas. In human medicine methotrexate is administered for the treatment of RA and psoriasis. Gastrointestinal toxicity is the most common complication encountered with the administration of methotrexate.

GLUCOCORTICOIDS

Prednisolone

Glucocorticoids and in particular prednisolone have both direct and indirect effects on the immune response. Glucocorticoids stabilize the cell membrane of endothelial cells and inhibit the production of local chemotactic factors, thus decreasing infiltration of neutrophils, monocytes, and lymphocytes. In allogeneic tissues the secretion of destructive proteolytic enzymes such as collagenase, elastase, and plasminogen activator is inhibited. Glucocorticoids also inhibit the release of arachidonic acid from membrane phospholipids. This inhibition prevents the synthesis of prostaglandins, thromboxanes, and leukotrienes, which are major mediators of inflammation. Glucocorticoids redistribute monocytes and lymphocytes from the peripheral circulation to the lymphatics and bone marrow. This redistribution affects primarily T cells. T-cell activation and cytotoxicity are also reduced. Glucocorticoids suppress cytokine activity and alter macrophage function. Prednisolone and prednisone are considered to be the first-line immunosuppressive agents for the treatment of immune-mediated and chronic inflammatory diseases in dogs and cats because of their general efficacy and low cost.

Immune-mediated hemolytic anemia and IMTP, autoimmune and allergic skin diseases, myasthenia gravis, allergic pneumonitis and bronchitis, immune-mediated arthritis, and systemic lupus erythematosus are just some of the indications for corticosteroid therapy in animals. Prednisolone has been used in both dogs and cats to slow allograft rejection; however, when administered as a single agent, prednisolone is not capable of preventing allograft rejection. For the prevention of allograft rejection in cats, prednisolone is administered with cyclosporine at an initial dose of 2.5 to 5 mg PO every 12 hours. This dose is generally reduced to 2.5 to 5 mg PO every 24 hours 30 days following transplantation. Over the next several months, following serum creatinine and blood urea nitrogen concentrations, the prednisolone dose is reduced to 2.5 mg PO every 24 hours or discontinued.

Although inexpensive and often effective, the chronic use of corticosteroids can result in severe complications, usually manifested as signs of iatrogenic hyperadrenocorticism. This complication, in addition to the fact that corticosteroids suppress multiple elements of the immune response, has led to the search for *steroid-sparing* immunosuppressive protocols.

CALCINEURIN INHIBITORS

Cyclosporine

Cyclosporine is bound in the cytosol of lymphocytes by cyclophilins (cyclosporine-binding proteins). The cyclosporine-cyclophilin complexes associate with calcium-dependent calcineurin-calmodulin complexes to impede calcium-dependent signal transduction. Transcription factors that promote cytokine gene activation are either direct or indirect substrates of the serine-threonine phosphatase

activity of calcineurin. This enzymatic activity is reduced by association of the cyclosporine-cyclophilin bimolecular complex with calcineurin. Via this mechanism of action, cyclosporine inhibits early T-cell activation (G_0 phase of the cell cycle) and prevents synthesis of several cytokines, in particular interleukin-2 (IL-2). Without stimulation by IL-2, further T-cell proliferation is inhibited, and T-cell cytotoxic activity is reduced. Cyclosporine may also exert an immunosuppressive effect as it stimulates mammalian cells to secrete transforming growth factor- β (TGF- β) protein. TGF- β is a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of antigen-specific cytotoxic lymphocytes. Cyclosporine is not cytotoxic or myelotoxic and is specific for lymphocytes. This specificity spares other rapidly dividing cells and allows nonspecific host defense mechanisms to continue to function.

Cyclosporine has gained widespread use in veterinary medicine. Combination cyclosporine and prednisolone immunosuppression has maintained normal function of MHC-nonmatched feline renal allografts for more than 12 years. Cyclosporine in combination with azathioprine, prednisolone, and antithymocyte serum has been used to maintain MHC-nonmatched canine renal allografts. Bone marrow transplantation has been performed successfully in cats with the use of cyclosporine immunosuppression. Cyclosporine has also been used to control corticosteroid-resistant IMHA and IMTP in dogs. Cyclosporine is available in an ophthalmic preparation (Optimmune, Schering-Plough, Kenilworth, NJ) for the control of keratoconjunctivitis sicca in dogs. Cyclosporine (10 to 20 mg/kg q24h PO) was found to significantly reduce the size and depth of perianal fistulas in dogs (Mathews and Sukhiani, 1997). Most dogs did not require further therapy, either medical or surgical, after 6 to 8 weeks of therapy. In a more recent study (Hardie et al., 2005) cyclosporine resolved or reduced the lesions in 25 of 26 dogs. However, residual or recurrent lesions were encountered that required long-term medical therapy or surgical resection. Cyclosporine (5 mg/kg q24h PO induction dose, reduced by 50% to 75% over weeks to months, depending on response) has been shown to be effective in the reduction of skin lesions and pruritus in dogs with atopic dermatitis (Steffan, Favrot, and Mueller, 2006). The use of cyclosporine for the treatment of other dermatologic diseases such as pemphigus foliaceus is under investigation (Guaguere, Steffan, and Olivry, 2004). There are reports that cyclosporine may be effective for the treatment of granulomatous meningoencephalitis (Adamo and O'Brien, 2004) and steroid-refractory inflammatory bowel disease (5 mg/kg q24h PO for 10 weeks; Allenspach et al., 2006).

Cyclosporine is available in two oral formulations: Sandimmune and Neoral (Sandoz). Both contain cyclosporine in a concentration of 100 mg/ml, but the two solutions are not biologically equivalent. Sandimmune consists of an olive oil base, and adsorption of cyclosporine requires emulsification of the agent by bile salts and digestion by pancreatic enzymes. The absorption percentage can be as little as 4%, and there is a tremendous variation in dose-trough whole-blood levels among individuals of the same species. Neoral is a microemulsion concentrate of cyclosporine that becomes a microemulsion

when in contact with gastrointestinal fluids. The microemulsion is directly absorbed through the gut epithelium, resulting in more sustained and consistent blood levels of the drug. When Neoral replaces Sandimmune as treatment, most feline renal transplant recipients have had a reduction in the dosage level necessary to maintain the same trough whole-blood levels. In addition, feline renal transplant patients have been administered Sandimmune at a dose of 10 to 15 mg/kg over 24 hours to initiate immunosuppression at the time of surgery. To achieve the same trough whole-blood levels of cyclosporine (approximately 500 ng/ml), Neoral is administered at a dose of 1 to 4 mg/kg over 24 hours. Neoral appears to be a more effective immunosuppressant than Sandimmune because of a more complete absorption, which results in a more sustained and predictable blood level. In addition, it is more economical to use.

To achieve immunosuppression with cyclosporine in dogs, I recommend attaining a 12-hour whole-blood trough level (measured just before the next oral dose) of at least 500 ng/ml. With Sandimmune, achieving this level requires an oral dosage of 10 to 25 mg/kg over 24 hours divided into two doses. Neoral can be initiated at 5 to 10 mg/kg over 24 hours divided into two doses. With either formulation gastrointestinal inflammation increases the dosage requirements, and blood levels of the agent must be measured starting 24 to 48 hours after initiation of therapy to ensure that adequate blood levels are achieved. Blood levels of cyclosporine should be measured at periodic intervals during the time of therapy. To reduce the cost of the cyclosporine necessary to treat medium-size- to large-dogs, I administer ketoconazole at a dose of 10 mg/kg over 24 hours in addition to the cyclosporine. Ketoconazole interferes with the hepatic metabolism of cyclosporine, and it reduces the dosage requirement of cyclosporine by as much as 60%. I have not encountered toxic effects with the coadministration of these agents, but it has been reported that the chronic administration of ketoconazole to dogs may result in cataract formation.

To achieve immunosuppression with cyclosporine in cats, I recommend attaining a 12-hour whole blood trough level of 250 to 500 ng/ml. With Sandimmune, obtaining this level requires an oral dosage of 4 to 15 mg/kg over 24 hours divided into two doses. Neoral can be initiated at 1 to 5 mg/kg over 24 hours divided into two doses. Again it is imperative to measure blood levels 24 to 48 hours after initiation of therapy to ensure that adequate blood levels have been achieved. Blood levels must also be measured periodically during the course of therapy. Based on recent pharmacokinetic studies in the cat, trough whole-blood concentrations of cyclosporine may not correlate well with drug exposure (Mehl et al., 2003). The whole-blood concentrations measured at 2 hours after administration of the drug may correlate better with drug exposure and give a better index for drug dosage and change in dose. The blood concentration of cyclosporine measured 2 hours after administration is recommended for therapeutic drug monitoring in human renal transplant patients.

Whole blood or plasma levels of cyclosporine can be determined by high-pressure liquid chromatography,

fluorescence polarization immunoassay, and specific monoclonal antibody radioimmunoassay. Most medical centers that serve humans perform cyclosporine assays and will serve veterinary needs.

Unlike the situation in humans, cyclosporine does not appear to be hepatotoxic in dogs and cats unless extremely high blood levels are maintained (>3000 ng/ml). Although not as frequently encountered in humans, cyclosporine can be nephrotoxic in the cat. Nephrotoxicity in the cat does not seem to be related to the level of the drug in whole blood and can occur at relatively low plasma concentrations. Cats with extremely high cyclosporine whole-blood concentrations (>4000 ng/ml) often show no toxicity at all. In my experience cyclosporine nephrotoxicity has only developed in one dog. This dog had a chylothorax that resulted in trough whole-blood concentrations of cyclosporine of greater than 3000 ng/ml. Levels higher than 1000 ng/ml can cause inappetence in cats. If levels of 1000 ng/ml are maintained for several weeks or months, opportunistic bacterial and fungal infections can occur. As in humans, cyclosporine could promote the development of neoplasia, particularly lymphomas, in cats and dogs. The administration of high levels (1 to 2 mg/kg over 24 hours) of prednisolone with cyclosporine increases the likelihood of tumor formation. As in humans, cyclosporine has resulted in a marked increase in hair growth in several of my feline renal transplant recipients. When administered to dogs, cyclosporine can result in severe gingival hyperplasia, fibropapillomatosis, and severe or fatal pyoderma, especially when combined with azathioprine (Gregory et al., 2006).

Cyclosporine has a distinctly unpleasant taste to both humans and animals, necessitating administration in gelatin capsules. Novartis supplies capsules containing 25 or 100 mg of cyclosporine. For most cats these capsules are too large. I place the oral solution in No. 0 or No. 1 gelatin capsules. Some cats need only a very small dose of cyclosporine (1- to 3-mg/dose). Measuring and administering this small amount (0.01 to 0.03 ml) of a drug is very difficult and imprecise. Sandimmune can be diluted and stored in olive oil; I usually make a 1-to-10 dilution. Neoral can be diluted in any oral solution, but it must be administered immediately after it is diluted because it is a microemulsion concentrate. I dilute Neoral in tap water.

Cyclosporine is also available in an intravenous solution (Sandimmune IV) that must be diluted in 0.9% sodium chloride or 5% dextrose in water. For the treatment of acute renal allograft rejection, I administer a dose of 6 mg/kg over 4 hours in the calculated maintenance fluid requirement. Intravenous cyclosporine is administered to control organ rejection episodes, for an acute hemolytic crisis, or during periods when a patient cannot tolerate oral medications.

Tacrolimus

Although tacrolimus, or FK-506 (Prograf, Fujisaw), is structurally different from cyclosporine, it shares a similar mechanism of action. Tacrolimus binds in the cytosol of lymphocytes with an immunophilin,

FK-binding protein (FKBP). As with the cyclosporine-cyclophilin complex, the tacrolimus-FKBP complex binds to calcineurin and inhibits its phosphatase activity. This inhibition directly and indirectly inhibits *de novo* expression of nuclear regulatory proteins and T-cell activation genes. The transcription of cytokines (IL-2, IL-3, IL-4, IL-5, interferon- γ , tumor necrosis factor- α [TNF- α], and granulocyte-macrophage colony-stimulating factor) responsible for lymphocyte activation is suppressed, as is the expression of IL-2 and IL-7 receptors. Tacrolimus *in vitro* is 50 to 100 times more potent as an inhibitor of lymphocyte activation than cyclosporine. Tacrolimus also inhibits B-cell proliferation and production of antibody by unknown mechanisms. Tacrolimus decreases the hepatic damage associated with ischemia-reperfusion injury, perhaps by inhibiting production of TNF- α and IL-6 by hepatocytes, and stimulates hepatic regeneration following liver injury. Experimentally allograft recipients from many species have been treated successfully with tacrolimus at doses several times less than those for cyclosporine. Tacrolimus has prolonged the survival of renal, liver, pancreas, heart, lung, and vascularized limb grafts in rodents, dogs, and nonhuman primates. In human organ recipients tacrolimus is superior to cyclosporine for the reversal of ongoing rejection. Also the steroid-sparing effect of tacrolimus seems to be greater than that of Sandimmune, but it may not be superior to that of Neoral. The toxicity of tacrolimus is similar to that of cyclosporine in humans.

Little if any use of tacrolimus has been applied to veterinary patients, but based on its effectiveness in experimental animal trials, it could be very useful in controlling a wide range of immune-mediated conditions. Tacrolimus may be particularly effective in controlling IMHA, IMTP, and immune-mediated arthritis because of its inhibition of antibody synthesis T-cell proliferation. Despite the potential benefits of tacrolimus for treating diseases in dogs, a major concern is the possible toxicity of the drug. A dose of 0.16 mg/kg every 24 hours intramuscularly or 1 mg/kg every 24 hours PO has been reported to be effective in prolonging renal allograft survival in beagle dogs. The side effects included anorexia, vasculitis, and intestinal intussusception. In a study using mongrel dogs the same doses were not effective in prolonging renal allograft survival, and most of the dogs developed severe vasculitis leading to fatal myocardial infarction, hepatic failure, and intussusception. Combination therapy with cyclosporine appears to have an additive effect with less toxicity. Blood levels of tacrolimus are assayed at human medical centers with the use of monoclonal immunoassays. The effective serum trough level of tacrolimus in dogs is approximately 0.1 to 0.4 ng/ml, about 100 times lower than that of cyclosporine. Trough levels of 2 ng/ml or greater can result in death. Used topically in a 0.1% solution, tacrolimus has safely controlled the lesions of discoid lupus erythematosus and pemphigus foliaceus in dogs (Rosenkrantz et al., 2004). Tacrolimus is also available in a topical 0.02% aqueous suspension for the effective treatment of dogs with keratoconjunctivitis sicca (Berdoulay, English, and Nadelstein, 2005).

INHIBITORS OF CYTOKINE AND GROWTH FACTOR ACTION

Sirolimus

Sirolimus, or rapamycin (Rapamune, Wyeth-Ayerst) is a macrocyclic antibiotic with a structure similar to that of tacrolimus that also binds in the cell cytosol to FKBP. However, sirolimus and tacrolimus affect different and distinct sites in the signal transduction pathway. The immunosuppressive activity of sirolimus appears to be a consequence in part of the sirolimus-FKBP complex blocking the activation of the mammalian target of rapamycin, (mTOR). mTOR is a serine/threonine protein kinase and is involved in the regulation of cell proliferation through the initiation of gene translation in response to amino acids, growth factors, cytokines, and mitogens. The kinase activity of additional cell cycle regulatory proteins cyclin-dependent kinase-2 and cyclin-dependent kinase-4 is also inhibited by sirolimus. Sirolimus blocks IL-2 and other growth factor-mediated signal transduction (signal 3 of the allograft rejection response) and the calcium-independent CD28/B7 (CD80/CD86) costimulatory pathway. Cyclosporine and tacrolimus block T-cell cell cycle progression at the G₀ to G₁ stage; sirolimus prevents cells from progressing from G₁ to the S phase. Sirolimus blocks T-cell activation by IL-2, IL-4, and IL-6 and stimulation of B-cell proliferation by lipopolysaccharide. Sirolimus directly inhibits B-cell immunoglobulin synthesis caused by interleukins.

Sirolimus has been shown to prevent acute, accelerated, and chronic rejection of skin, heart, renal, islet, and small bowel allografts in rodent, rabbit, dog, pig, and nonhuman primate graft recipients. It has also been shown to be efficacious in models of autoimmunity; insulin-dependent diabetes, and systemic lupus erythematosus. The antagonism of cytokine and growth factor action by sirolimus is not limited to cells of the immune system. It inhibits the proliferation of fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells induced by growth factors such as platelet-derived growth factor and fibroblast growth factor. Sirolimus has been very effective in preventing intimal smooth muscle proliferation (arteriosclerosis) following mechanical or immune-mediated arterial injury. In human clinical trials supplementation of cyclosporine-based protocols is associated with a reduction in acute allograft rejection; however, the combination of the two drugs increases the risk for nephrotoxicity, hemolytic-uremic syndrome, and hypertension. Other reported side effects include hyperlipidemia, thrombocytopenia, delayed wound healing, delayed graft function, mouth ulcers, pneumonitis, and interstitial lung disease. Everolimus, another inhibitor of mTOR, is a derivative of sirolimus.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF), also known as RS-61443 or mycophenolic acid (Cellcept, Roche), is a prodrug hydrolyzed by liver esterases to mycophenolic acid. MMF is cytostatic for lymphocytes, owing to its inhibition of inosine monophosphate dehydrogenase, an enzyme

necessary for *de novo* purin e biosynthesis. MMF is a relatively selective inhibitor of T- and B-cell proliferation during the S phase of the cell cycle via its ability to prevent guanosine and deoxyguanosine biosynthesis. MMF has been shown to reduce allograft rejection in multiple animal models, demonstrating the most effect when combined with cyclosporine, tacrolimus, and/or sirolimus. MMF was developed in part as a nonmyelotoxic replacement for azathioprine in human allograft patients. Early clinical trials in human renal allograft recipients showed a decrease in biopsy-proven acute rejection episodes in patients receiving MMF in place of azathioprine. At therapeutic doses MMF can be toxic to animals. The primary dose-limiting effects are anemia and weight loss in rats; leukopenia, diarrhea, and anorexia in monkeys; and gastrointestinal hemorrhage, anorexia, and diarrhea in dogs. To reduce the toxic effects, the dose can be lowered, or mycophenolic acid can be given in combination with other immunosuppressive agents. MMF (10mg/kg q12h PO) has been used in combination therapy in veterinary medicine to control renal allograft rejection in dogs (Broadbuss et al., 2006).

There are anecdotal reports of the use of MMF for the treatment of RA, myasthenia gravis, and renal allograft rejection in the dog. In humans MMF has been used to treat scleroderma lung disease and Evans syndrome. MMF can also inhibit growth factor-induced smooth muscle and fibroblast proliferation. Sirolimus and MMF in combination are extremely effective in preventing arterial intimal smooth muscle proliferation following mechanical injury. This has marked implications for the control of chronic allograft rejection in humans.

Leflunomide and Leflunomide Analogs

Leflunomide is a synthetic organic isoxazole that the intestinal mucosa metabolizes to the active form, A77 1726. Leflunomide mediates at least part of its antiproliferative activity during the S phase of the cell cycle by inhibiting the *de novo* pathway of pyrimidine biosynthesis. The target of A77 1726 in this pathway is the enzyme dihydroorotate dehydrogenase. At higher concentrations leflunomide is also an inhibitor of tyrosine kinases associated with growth factor receptors. In addition to T and B lymphocytes, leflunomide also has an antiproliferative effect on smooth muscle cells and fibroblasts, which is also caused by the result of inhibition of the pyrimidine biosynthetic pathway in these cells. Leflunomide is currently approved for the treatment of RA in humans. It has been shown to be an effective disease-modifying antirheumatic drug free from the side effects commonly associated with currently approved immunosuppressants.

In addition to its efficacy in humans and animal models with autoimmune diseases, leflunomide has been found to control acute, ongoing, and chronic allograft rejection of the kidney, skin, heart, vessels, and lung in small- and large-animal models. I have used leflunomide to successfully treat steroid-resistant autoimmune hemolytic anemia and systemic histiocytosis in dogs. In combination with cyclosporine, leflunomide has completely prevented the rejection of canine MHC-

nonmatched renal allografts in both experimental and clinical studies. At doses used in humans, leflunomide causes gastrointestinal toxicity in dogs as a result of the accumulation of a metabolite trimethylfluoroaniline (TMFA). Fortunately the canine lymphocyte is far more sensitive than the human lymphocyte to the effects of the active agent A77 172, and much lower oral doses are equally effective in achieving immunosuppression. I currently use a dose of 4 mg/kg PO over 24 hours and adjust the dose as needed to obtain a 24-hour serum trough level of 20mg/ml. Early studies in the cat suggest that TMFA does not present the toxicity problem encountered in dogs; cats metabolize the drug much more slowly and may only require 2 mg/kg/day once or twice a week to maintain effective blood concentrations. Leflunomide (70 mg/cat once weekly PO) in combination with methotrexate (7.5 mg/cat once weekly PO) has been used to treat feline RA (Hanna, 2005). Both cats and dogs with diminished renal function may be subject to TMFA toxicity since it is excreted by the kidneys. Leflunomide is marketed under the trade name Arava (Aventis Pharmaceuticals). The use of leflunomide in dogs has been very expensive; however, a generic form of the drug is now available, reducing the cost of therapy by approximately 80%.

Leflunomide analogs currently are under development for transplantation applications. A combination of cyclosporine and FK778, a leflunomide analog, significantly prolonged MHC-mismatched canine renal allograft survival.

INVESTIGATIONAL COMPOUNDS

FTY 720 is derived from myriocin, a fungus-derived sphingosine analog. After phosphorylation, FTY 720 engages lymphocyte sphingosine-1-phosphate receptors and profoundly alters lymphocyte trafficking, acting as a functional sphingosine-1-phosphate antagonist. FTY 720 sequesters naïve and activated CD4+ and CD8+ T and B cells from the blood into lymph nodes and Peyer's patches without affecting their functional properties. It is important to note that FTY 720 does not impair cellular or humoral immunity to systemic viral infection nor does it affect T-cell activation, expansion/proliferation, or immunologic memory.

FTY 720 synergizes effectively with inhibitors of T-cell activation and proliferation to prevent allograft rejection in a wide range of animal models. In combination with subtherapeutic concentrations of cyclosporine, FTY 720 has been shown to delay or prevent the rejection of skin, heart, small bowel, liver, and kidney allografts in rats, dogs, and nonhuman primates. Similar results have been seen when FTY 720 is combined with sirolimus and tacrolimus. FTY 720 is metabolized extensively in the liver via cytochrome enzymes that are not involved in the metabolism of cyclosporine, sirolimus, or tacrolimus; therefore variations in drug concentrations when these agents are coadministered are unlikely to occur. The pharmacokinetic profile of FTY 720 is characterized by linear dose-proportional exposure over a wide range of doses, only moderate interpatient variability, and a prolonged elimination half-life (89 to

150 hours). These factors suggest that FTY 720 will be administered once daily without the need for monitoring blood concentrations or dose titration. Human renal transplant patients experienced a significant reduction in peripheral blood lymphocyte counts by up to 85%. In the initial clinical trials in human renal transplant patients, FTY 720 was well tolerated and did not cause any significant toxicity, allograft loss, increase in infection rates, or other complications such as diabetes. However, when administered in combination with cyclosporine in later studies, possible toxic side effects were revealed that may negate the development of the drug for transplantation in humans. Pharmacokinetic and pharmacodynamic studies are currently under way in cats.

COMBINATION THERAPY

Most of the currently used or soon-to-be-available immunosuppressive agents have differing mechanisms of action and are effective at different stages of the cell cycle. Experimentally and clinically, combining agents often results in more effective immunosuppression with fewer drug-induced side effects. In human transplant patients cyclosporine or tacrolimus is currently considered to be the first line of immunosuppressive agents. To increase their effectiveness and decrease toxicity, azathioprine, sirolimus, prednisolone, and/or MMF are added to antirejection protocols. Few of the new non-myelotoxic agents have been used in veterinary patients, but many published experimental animal trials investigating autoimmune disease and organ transplantation provide indications and insight into their use. Based on experimental and clinical experience in canine MHC-nonmatched organ transplantation, the combination of cyclosporine and leflunomide or cyclosporine and azathioprine is extremely effective in preventing renal allograft rejection.

Blood-Typing and Crossmatching

URS GIGER, *Philadelphia, Pennsylvania*

Transfusion therapy has assumed an increasingly important role in the life support of companion animals since the early 1980s. The use of blood products in treating critically ill animals and supporting those undergoing surgical and other procedures has increased tremendously. Despite this trend, blood products represent a limited and sometimes unavailable resource. Since these products are biologicals from donor animals, transfusion also carries the inherent risks of transmitting infectious agents and causing adverse reactions. Accordingly, the need for blood-typing, crossmatching, and testing of donors for transmittable diseases is pivotal to insuring safe and efficacious transfusions. The Association of Veterinary Hematology and Transfusion Medicine and American Association of Veterinary Blood Banking have been established towards these ends, and these groups are developing blood-banking and transfusion therapy standards. Veterinary clinicians play a key role in the provision of safe and effective transfusion; therefore they must be aware of transfusion principles. This chapter summarizes some of the advances in blood compatibility testing in dogs and cats and offers practical recommendations for transfusion therapy.

CANINE BLOOD TYPES

Blood types are genetic markers on erythrocyte surfaces that are antigenic and species specific. A set of blood types of two or more alleles makes up a blood group system. More than a dozen blood group systems have been described in dogs. The various systems are generally referred to as dog erythrocyte antigens (DEAs), with the abbreviation DEA followed by a number (note: there is no DEA 2 system). No reagents are currently available for many antigens, and additional blood types continue to be recognized. For all blood group systems other than the DEA 1 system, red blood cells from a dog can be either positive or negative for that blood type. For instance, for the DEA 7 system, a dog's red blood cells can be DEA 7 positive or DEA 7 negative, and these blood types appear to be codominantly inherited. In the DEA 1 system, which represents an exception, DEA 1.1 (A_1) and 1.2 (A_2) are allelic, and there may even be a DEA 1.3 (A_3). Thus a dog can be DEA 1.1 positive or negative, and DEA 1.1-negative dogs can be DEA 1.2 positive or negative.

Only very limited surveys report on the frequency of these blood types with some suggestions of geographic

and breed-associated differences. Some of the blood types are seen rarely (e.g., DEA 3), whereas others occur very commonly (DEA 4). In Japan additional blood-group systems have been proposed, but their associations to the DEA systems and their clinical importance have not been documented. Most recently an apparently new common red cell antigen that seems to be missing in some dalmatians, hence named *Dal* red cell antigen, has been identified.

Strongly antigenic blood types are of great clinical importance because they can elicit a potent alloantibody response. These alloantibodies may be of the immunoglobulin (Ig)G or IgM class and may be hemagglutinins or hemolysins. Clinically the most antigenic blood type in dogs appears to be DEA 1.1. Based on experimental and clinical data, dogs can become sensitized after receiving a mismatched transfusion (i.e., a blood unit positive for one or more blood types not found on the recipient's red blood cell). Sensitizing dogs in experimental studies in the 1950s led to the documentation of some transfusion reactions caused by blood-group incompatibilities and to the characterization of new blood types.

There are no clinically important naturally occurring alloantibodies (also known as isoantibodies) present before sensitization of a dog with a transfusion. Furthermore, pregnancy does not cause sensitization because of a complete placenta in dogs and thus does not induce alloantibody production. Transfusion of DEA 1.1-positive cells to a DEA 1.1-negative dog invariably elicits a strong alloantibody response. After a first transfusion, anti-DEA 1.1 antibodies develop after more than 4 days and may cause a delayed transfusion reaction. However, a previously sensitized DEA 1.1-negative dog will develop an acute hemolytic reaction after transfusion of DEA 1.1-positive blood. Transfusion reactions may also occur after a sensitized dog receives blood that is mismatched for a red blood cell antigen other than DEA 1.1. For instance, a whippet developed an alloantibody against a common red blood cell antigen, resulting in a general incompatibility with any donor except a littermate. Similarly a dog with DEA 4-negative blood, another common antigen, showed an acute hemolytic transfusion reaction after receiving a second DEA 4-positive blood transfusion. Because administration of a small (<1 ml) amount of incompatible blood can result in life-threatening reactions, the practice of giving small "test volumes" of donor blood to assess blood-type compatibilities is unacceptable.

CANINE BLOOD-TYPING PROCEDURE

To ensure efficacious and safe transfusions, blood donor and recipient should be blood typed. Canine blood-typing is generally based on serologic identification by agglutination reactions. Originally serum from sensitized dogs was used for typing, but such polyvalent alloantibodies vary from batch to batch and therefore are not optimal. Recently monoclonal antibodies against DEA 1.1 have been developed at Kansas State University and at the University of Lyon. Because of the strong antigenicity of DEA 1.1, typing of *donors* for DEA 1.1 is strongly recommended. Whenever possible, the *recipient* should also be typed to allow the use of DEA 1.1–positive blood for DEA 1.1–positive recipients. A blood-typing card has been available for a decade as a simple standardized in-practice kit (DMS Laboratories, Flemington, NJ) to classify dogs as DEA 1.1 positive or negative. This assay requires a small amount of anticoagulated blood (0.1 ml) and is based on an agglutination reaction that occurs within 2 minutes when DEA 1.1–positive erythrocytes interact with a murine monoclonal DEA 1.1 alloantibody. Based on limited data, it appears possible that this card may give a weak positive agglutination reaction with DEA 1.2–positive red cells. A new point-of-care cartridge for DEA 1.1 typing has recently been introduced (Alvedia, Lyon, France), which may make interpretation simpler.

Typing for DEA 1.1 is also available through most commercial and veterinary school laboratories. These laboratories had employed either the card method or a tube assay using reagents from Midwest Animal Blood Services, which requires the addition of a Coombs' reagent. Furthermore, a unique gel column technology, widely used in human blood banking, recently has been adopted for DEA 1.1 typing and found to be an excellent laboratory technique. This method uses a 4% red cell suspension in a standardized method with a monoclonal alloantibody for DEA 1.1 typing (which does not cross-react with DEA 1.2–positive cells) and gel columns, in which the agglutinating DEA 1.1–positive cells are retained on top of (or within) the gel by the reagent-induced hemagglutination. These cells are readily separated from the nonagglutinating (DEA 1.1–negative) cells, which pass through the gel after centrifugation (DiaMed, Cressier, Switzerland).

Dogs that are DEA 1.1 negative are considered universal blood donors for a previously untransfused dog. However such donors can still sensitize a recipient against other red cell antigens. Pregnancy does not sensitize a dog to develop alloantibodies.

Caution should be exercised during blood-typing whenever the patient's blood is autoagglutinating or has a very low hematocrit (<10%).

It is recommended to check for autoagglutination of blood with either buffer/saline on a slide or using the card test. Furthermore, with autoagglutination the control gel column may become positive, which negates interpretation of any typing results. Autoagglutinating blood first may be washed three times with (phosphate-buffered) physiologic saline. This procedure will help overcome apparent autoagglutination when performing the Coombs' test or cross-match tests within tubes in a laboratory setting. However, if autoagglutination after three washes persists at greater

than 1+, it is considered to reflect true autoagglutination. True autoagglutination precludes blood-typing (as well as crossmatching and Coombs' testing), because the sample will always appear as DEA 1.1–positive blood. In such circumstances DEA 1.1–negative blood should be used for transfusion until the patient no longer agglutinates and after the transfused cells are eliminated. At that point the patient's blood can be retyped.

DEA 1.1–positive blood from very anemic animals may not agglutinate when exposed to the DEA 1.1 or other reagents because of the prozone effect. In these cases some of the patient's plasma may be discarded before applying a drop of blood onto the card.

Finally recently transfused dogs may also create practical problems in blood-typing. Samples may display a mixed field reaction with only the transfused or recipient cells agglutinating.

Some veterinarians recommend using only canine donors that are negative for all testable DEAs except DEA 4 (as >98% of dogs are DEA 4–positive) to prevent sensitization against these blood types. Typing services and polyclonal antisera are available for DEA 1.1, 1.2, 3, 4, 5, and 7 (Midwest Animal Blood Services, Michigan) for extended typing. However, the clinical relevance of these and other blood groups to any given canine patient is usually identified following crossmatching of a previously-transfused dog. The use of these more extensive blood-typing products requires some expertise and experience. For these and other reasons the author does not support routine typing for blood types other than DEA 1.1. Additional typing unnecessarily removes many active and potential canine donors, is cost prohibitive, and does not eliminate the need for crossmatching following the first transfusion. There are no supporting published clinical studies demonstrating that transfusion reactions can be reduced substantially by extended blood-typing. Similarly, human patients are only typed for the ABO and Rh blood group systems, although greater than two dozen other blood group systems are known.

FELINE BLOOD TYPES

Although the feline AB blood group system remains the most clinically relevant and best recognized system, additional feline blood groups have recently been described. These systems may contribute to blood incompatibility reactions. Cats lacking a certain antigen on the red cell surface may have naturally occurring or induced alloantibodies (also known as *isoantibodies*) against the missing blood antigen (type). These alloantibodies can be responsible for acute hemolytic transfusion reactions and anti-A–mediated hemolysis of the newborn, a condition known as neonatal isoerythrolysis (NI).

The AB blood group system is recognized as the major blood group system and contains three types: type A, type B, and the rare type AB. The “a” allele is dominant over the “b” allele. Thus cats with type A blood have the genotype a/a or a/b, and only homozygous b/b cats express the type B antigen on their erythrocytes. A third allele is recessive to “a” and codominant to “b” and leads to the expression of both A and B substances on erythrocytes in the extremely rare AB cats. Thus AB cats are not produced by mating a type A to a

type B cat unless the A cat carries the rare AB allele. Type AB blood has been seen in many purebred and domestic shorthair (DSH) cat breeds known to have type B blood. No type O or null type cats have been recognized. The molecular basis of the feline AB blood group has recently been determined and DNA testing is now available, which may be helpful for breeding purposes (Vet Gen Lab, UC, Davis).

An extensive survey of more than 20,000 DSH and purebred cats in the United States has been done at my institution over the past two decades, and many additional smaller studies have screened the blood types of cats in certain geographic areas, including DSH and purebred cats. Although type A is the most common blood type, the frequency of types A and B in DSH cats varies worldwide and even among regions. However, in purebred cats the frequency of A and B blood types varies greatly, although not as much geographically, probably because of the international exchange of breeding cats. The type B frequency may vary from none, as in the Siamese and related breeds, to 40%, as in the British shorthair and Devon rex breeds. In contrast, type AB is extremely rare, with a frequency of less than 1% in DSH and some purebred cats. Furthermore, kitten losses caused by A-B incompatibility and the resultant changes in breeding practices influence the frequency of A and B in various breeds. Indeed A-B incompatibility results in an unusual selection against heterozygous kittens and thereby an allele disequilibrium.

Most blood donors have type A blood, but some institutions also keep cats with the rare type B and type AB as donors. All blood donors must be typed, as there are no universal donor cats. Table 56-1 denotes the frequency of A and B blood types in various geographic locations and various cat breeds.

Additional feline blood groups have been suspected despite A-B compatibility. This conclusion is based on incompatible blood crossmatching results or the recognition of hemolytic reactions following transfusion in A-B compatible cats. Some cats develop blood incompatibilities to practically all potential donors, making safe and effective transfusion nearly impossible. These cats likely lack a high frequency or common red cell antigen. Very recently the author's laboratory documented a novel *Mik* antigen in most but not all DSH cats. Blood transfusions of *Mik*-positive blood to cats lacking the *Mik* antigen resulted in acute hemolytic transfusion reactions. The presence of naturally occurring anti-*Mik* alloantibodies has been documented in several additional *Mik*-negative cats since our initial report. The clinical relevance of the *Mik* antigen and corresponding alloantibody underlie our concern for potential hemolytic transfusion reactions in cats. Recent unpublished studies by the author's laboratory suggest other feline blood types along with the presence of naturally-occurring or induced alloantibodies.

BLOOD-TYPING PROCEDURES

Blood typing is recommended for both donor and recipient cats to allow for an appropriately matched transfusion, and for breeding cats to ensure blood-compatible mates and prevent isoerythrolysis in newborn kittens. Feline blood-typing generally is based on serologic identification by agglutination reactions. Originally serum from sensitized cats was used for A and B typing; but the lectin *Triticum vulgaris* has replaced the anti-B serum. Monoclonal anti-A and anti-B antibodies have been developed at Kansas State University and Lyon, France and are used in the

Table 56-1

Selected Blood Type A and B Frequencies in Cats*

* Ignoring the rare AB type.

blood-typing gel column and cartridge kits. Several AB typing techniques have been developed for use in practice or in the laboratory setting.

For the tube assay for feline blood-typing, washed red cell suspensions are mixed with anti-A serum from type B cats or antiserum from *T. vulgaris*, as anti-A and anti-B, respectively. Although this is the gold standard, currently it is only performed in the author's reference laboratory and at a few other sites. The same reagents at higher concentrations can also be used with whole blood in a simple slide agglutination screening test, but autoagglutination may preclude correct interpretation. A novel tube assay has become available using a red cell suspension (Shigeta Pharmaceutical,) but this test is not commercially available in the United States and appears to be somewhat cumbersome for use in private practice.

For over a decade, a commercial feline AB blood-typing card test has been available for in-practice use (DMS Laboratories), although the A reagent has been switched from anti-A serum to two anti-A monoclonal antibodies. This assay requires a small amount of anticoagulated blood (0.1 ml) and is based on an agglutination reaction that occurs within 2 minutes when type A- and/or B-positive erythrocytes interact with two murine monoclonal anti-A alloantibodies and/or lectin in the respective wells. While simple to perform in the practice setting, complications similar to those observed with canine typing cards have been observed. Occasionally no agglutination in either well occurs, suggesting a faulty card; or slight agglutination occurs in both wells, suggesting an AB blood type when in fact the cat has autoagglutination. This seems to be of particular concern on cards in which lectin and anti-A serum were replaced with monoclonal antibodies. Autoagglutination should be revealed by agglutination in the autocontrol well; and, if noted, the red cells can be washed three times with saline and the blood retested. There are other rare misinterpretations that occur using blood-typing cards. Sometimes type AB cats are not recognized by the card kit and are erroneously typed as either A or B. Blood from severely anemic cats may not agglutinate because there might be an excess of antibody present compared to the number of red cells (i.e., prozone effect).

In addition to card tests, other technologies have been used for feline blood-typing. A point-of-care typing cartridge with monoclonal anti-A and Anti-B antibodies has recently been introduced (Alvedia, Lyon, France). Most recently the gel column technology has been introduced for feline AB typing (DiaMed, Switzerland). This method originally used dilute unwashed red cell suspensions and a gel column with either a polyclonal anti-A alloantibody and the lectin *T. vulgaris* as anti-B. Now this test uses anti-A and anti-B monoclonal antibodies. This provides clear differentiation among type A-, type B-, and type AB-positive blood (if the autoagglutination control column using saline is negative). This test is restricted to larger laboratories because a special centrifuge is needed for the gel columns. In various surveys and comparative studies in the author's laboratory, this technique was found to be a highly reliable and easily standardized method. The same gel column technique has also been effectively used with anti-DEA 1.1 monoclonal antibodies to screen for DEA 1.1-positive and DEA 1.1-negative dogs. Finally, molecular genetic typing methods have become available (Vet Gen Labs, UC, Davis).

Typing for other feline blood types is not commercially available at the time of this writing, but is offered at the University of Pennsylvania laboratory (www.vet.upenn.edu/penngen). More studies are required to develop simple, widely-available typing tests. There is also a need to evaluate the clinical indications for screening for additional blood types before these are included in every compatibility workup.

In contrast to dogs, cats possess naturally occurring alloantibodies against the blood type antigen they lack. In particular, all type B cats develop very strong anti-A antibodies with high hemolysin and agglutinin titers (>1:32) after a few weeks of age. These anti-A antibodies are responsible for the life-threatening incompatibility reactions such as NI and acute hemolytic transfusion reactions.

A mismatched transfusion with type A blood given to a type B cat (but also type B blood given to a type A cat) results in a very serious acute hemolytic transfusion reaction. A *first* transfusion of as little as *1 ml of incompatible blood* may cause a fatal reaction without prior sensitization. Affected cats may show anaphylactic signs of hypotension, bradycardia, vomiting, and convulsions followed by hemolytic signs of pigmenturia and icterus without a transfusion-associated rise of the hematocrit. Thus mismatched transfusions are dangerous, as well as ineffective.

Kittens of blood types A and AB, receiving anti-A alloantibodies through the colostrum from type B queens (including primiparous queens), during the first 16 hours of life are at risk for NI. Hemolysis of the newborn is characterized by dark pigmenturia, anemia, icterus, anorexia, and sudden death within the first week of life. Survivors may develop tail tip necrosis.

In contrast to type B cats, type A cats have generally weak anti-B alloantibodies with low anti-B titers of 1:2. These antibodies cause shortened survival of transfused B cells in type A cats with signs of acute hemolytic anemia. Anti-B antibodies have not been associated with NI in type B kittens born to type A queens.

BLOOD CROSSMATCHING TEST

Blood-typing tests reveal the *blood group antigens* on the red blood cell surface, and blood crossmatching tests indicate the *serologic* compatibility or incompatibility between donor and recipient. Thus the crossmatching tests check for the presence or absence of naturally occurring and induced alloantibodies in serum (or plasma). These antibodies may be hemolysins and/or hemagglutinins and can be directed against known blood groups or other red blood cell surface antigens. The *major crossmatch* tests for alloantibodies in the recipient's plasma against donor cells, whereas the *minor crossmatch* looks for alloantibodies in the donor's plasma against the recipient's red blood cells. Generally tube segments from collection bags are used for this purpose in dogs. Blood in a small EDTA tube is saved at the time of the blood collection by a small open or specially prepared closed system in cats.

Clearly, collecting and storing even small quantities of blood units for compatibility testing are technically difficult and further reduce the amount of blood to be transfused. Several crossmatch techniques are used in clinics and laboratories to screen for alloantibodies. For reference

laboratories, a standardized tube crossmatching procedure has been proposed and is in use at many sites. This crossmatching test requires considerable technical expertise and experience, and is usually accomplished through a veterinary laboratory along with blood typing. The test is performed on EDTA-anticoagulated blood from the recipient and potential donor. Dilute red cell suspensions and plasma (or serum) are used, and some protocols include Coombs' reagents to enhance the reaction. Furthermore the author has evaluated the novel (DiaMed) gel column technique and found it in studies to be a simple, sensitive, and standardized laboratory method to crossmatch dogs and cats. The saline gel tests can be used for crossmatching in any species, but gel columns containing species-specific Coombs' (canine or feline antiglobulin) reagents may be more sensitive in recognizing blood incompatibilities, particularly in cats. This test is also applicable for the diagnosis of immune-mediated hemolytic anemias in cats and dogs. Persistent autoagglutination or severe hemolysis may preclude crossmatch testing. Initial studies performed in our laboratory used the saline gel column system and we were able to readily detect any A-B and also *Mik*-related incompatibilities. In more recent investigations we introduced a feline-specific antiglobulin gel column, which seems to be a sensitive but still simple and specific test. These methods hold promise for detecting both known and additional blood incompatibilities in laboratories. Most recently a gel-based tube major crossmatch assay for in-practice use has been introduced (DMS Laboratories, Flemington, NJ), but no studies have been published regarding use of this test. A simple slide test is sometimes used in clinical practice prior to feline transfusions and is described below.

A major crossmatch incompatibility is of greatest importance because it predicts that the transfused donor cells will be attacked by antibodies in the patient's plasma, thereby causing an acute hemolytic transfusion reaction that could become life threatening. As stated previously, fatal reactions may occur with less than 1 ml of incompatible blood, and therefore compatibility testing by administering a small amount of blood is inappropriate. Animals with an incompatible crossmatch should not be transfused with blood from that particular donor; instead, another potential donor should be tested for blood compatibility. The diligent application of appropriate blood-typing and crossmatching tests can ensure that blood is effectively and safely transfused in dogs and cats. A minor crossmatch incompatibility may be of lesser concern because the donor's plasma volume is small, particularly in packed red blood cell products, and the plasma is markedly diluted in the patient. The presence of autoagglutination or severe hemolysis may preclude crossmatch testing. There are some important differences in expected crossmatch test results between dogs and cats.

Dogs

The initial blood crossmatch between two dogs that have never before received a transfusion should be compatible because dogs do not have clinically important naturally occurring alloantibodies. Therefore one might omit a crossmatch before the first transfusion of a patient if

the donor has not been transfused previously. Because the crossmatch does not determine the blood type of the patient and donor, a compatible crossmatch does not prevent sensitization of the patient against donor cells within 1 to 2 weeks. Therefore previously transfused dogs should *always* be crossmatched, even when they receive blood from the same donor, and should never be used as blood donors. The time span between the initial transfusion and incompatibility reactions may be as short as 4 days, and the risk of a reaction lasts for many years (i.e., years after the last transfusion, as alloantibodies may be present). Obviously a blood donor should never have received a blood transfusion to avoid sensitization.

Cats

Since cats have naturally occurring A or B alloantibodies (unless the cat has blood type AB), a blood crossmatch test will detect an A-B mismatch. In fact, mixing a drop of donor/recipient blood with donor/recipient plasma, respectively, will detect any A-B incompatibility in a patient over 3 months of age because by that time the cat will have developed its naturally occurring alloantibodies. Any previously transfused (>4 days earlier) cat needs to be crossmatched before receiving additional blood, even when getting it from the same donor, and a major and minor crossmatch should be performed. Because of the recent discovery of additional feline blood groups such as *Mik* with naturally occurring alloantibodies present in many cats, crossmatching of any cat to be transfused with AB-matched blood may be the proper recommendation in the near future. This is particularly likely to occur once standardized Coombs'-based tests are more available.

Unlike the situation in dogs, the first crossmatching test between cats may demonstrate transfusion incompatibility, even before the first transfusion, due to naturally-occurring alloantibodies. This result may be caused by anti-A alloantibodies, anti-B alloantibodies, *Mik* alloantibodies, or reactions to some other common red cell antigens. Thus, if blood-typing is unavailable in an urgent clinical setting or if the results from a point of care typing test are difficult to interpret, at least a crossmatch test can be done. Because of strong anti-A agglutinins in any cat older than 3 months, these blood type incompatibilities in cats often can be recognized by a simplified crossmatch procedure. This is done by mixing 2 drops of plasma with 1 drop of blood from either the recipient or the donor on a slide at room temperature.

The issue of naturally occurring alloantibodies in cats also impacts plasma transfusions. For this reason, only AB plasma can be safely transfused to cats; in fact, since additional naturally occurring alloantibodies may exist in a plasma unit, plasma crossmatching may need to be considered.

ALTERNATIVES TO BLOOD TRANSFUSIONS

Since blood is a scarce resource and may cause various transfusion reactions, alternatives should be considered before administering a transfusion. Indeed, in many cases specific treatment of the underlying disease and other supportive care are all that is needed. Crystalloid

and colloid fluids are appropriate in cases in which hypovolemia and low oncotic pressure are the major concerns. Oxygen therapy adds little to oxygen delivery in an anemic patient and therefore should only be considered when there is concomitant pulmonary-induced hypoxemia, as is sometimes observed in patients with lung injury associated with immune-mediated hemolytic anemia. Human recombinant erythropoietin may have a place in the management of some anemias, as with the anemia associated with chronic renal failure. However, the effects of erythropoietin are not evident for weeks, and it is therefore an ineffective therapy in emergency situations. This therapy has also induced cross-reacting antibodies against erythropoietin resulting in aplastic anemia.

In case of tissue hypoxia caused by a lack of red cells (hemoglobin), bovine ultrapurified hemoglobin solution (Oxyglobin, Biopure, MA) can be used as a blood substitute in place of packed red blood cells. Oxyglobin is approved for dogs and has been shown to be effective and safe as a transient oxygen carrier in various clinical case series; however, because of its strong oncotic properties at higher doses, hypervolemia and pulmonary edema are of particular concern in cats and any patient with a compromised cardiovascular system. Furthermore, the benefit of reaching capillaries with oxygen transported by free hemoglobin rather than red cells may be countered by some of the other compromising cardiovascular effects of Oxyglobin.

Although in human medicine various recombinant human products are available as alternatives for plasma transfusion, these options have not been evaluated completely and may be unsafe or cost prohibitive in dogs and cats. Human albumin has been used in cases of severe hypoalbuminemia, but major concerns have been raised about the development of reactions against this human product in animals. Recombinant coagulation factors have dramatically reduced the use of fresh frozen plasma in humans. Recombinant human factor VIIa (FVIIa) has been evaluated in dogs with factor VII deficiency as well as some other conditions. While there is no commercial canine or feline Ig concentrate, human intravenous Ig has been used successfully in the acute management of dermal and systemic toxic drug reactions in some veterinary situations. Again these are human products that carry the risk for reactions, particularly after repeated use.

In conclusion, to ensure safe and effective transfusions, every blood donor and recipient should be blood typed and in dogs (if previously transfused) also cross-matched. Crossmatching may be indicated at the time of the first feline transfusion. Small volume test transfusions are dangerous and the practice is unacceptable. Simple and standardized typing and crossmatching techniques have become available and will avoid most hemolytic transfusion reactions caused by blood-type incompat-

ibilities. Appropriate controls must be performed to exclude autoagglutination and typing and compatibility misinterpretation. True (persistent) autoagglutination precludes blood-typing, crossmatching, and Coombs' testing. Unlike the situation in dogs, major and minor crossmatching tests can show incompatibilities before any transfusion in cats. Transfusion of blood that is cross-match incompatible is unsafe and ineffective.

*Original studies by the author were supported in part by the National Institutes of Health (RR02512).

Immune-Mediated Hemolytic Anemia

ELLEN MILLER, *Longmont, Colorado*

PATHOPHYSIOLOGY

Immune-mediated hemolytic anemia (IMHA) is a life-threatening hematologic disease of dogs and cats. Erythrocytes are destroyed by a type II hypersensitivity reaction that results in extravascular or intravascular hemolysis. Extravascular hemolysis occurs when immunoglobulin (Ig)- or complement-coated erythrocytes are removed by phagocytic cells of the mononuclear phagocyte system. If the red blood cells (RBCs) are coated with enough IgG or IgM molecules to fix complement, intravascular hemolysis also may result. Ten to twenty percent of dogs with IMHA have the intravascular form.

Primary IMHA is a true autoimmune reaction against RBCs. The majority of dogs with IMHA (60% to 75%) are thought to have this form of the disease since no underlying etiology can be identified. In secondary IMHA erythrocytes are destroyed as “innocent bystanders” in an immune reaction against some foreign protein that may be adherent to the erythrocyte surface. Usually the triggering protein is a result of viral or bacterial infection, drug administration, or neoplastic processes. Secondary IMHA is the more common form in cats.

It is important to realize that hemolytic anemia is not caused only by immunologic mechanisms. Other diseases, drugs, or toxins associated with hemolytic anemia are listed in Box 57-1. In the diagnostic approach to the patient with hemolytic anemia one should consider all the other potential etiologies.

DIAGNOSIS OF IMMUNE-MEDIATED HEMOLYTIC ANEMIA IN DOGS

Clinical Presentation

Signalment

Immune-mediated hemolytic anemia is a disease of middle-age dogs (median age of affected dogs is 6 to 7 years). Although any breed may be affected, cocker spaniels, English springer spaniels, collies, poodles, Old English sheepdogs, and Irish setters are overrepresented. Most reports of canine IMHA have noted a predominance of female dogs. A recent study of cats with primary IMHA reported a median age of 2 years (Kohn et al., 2006). No single breed was shown to be at risk. Eleven male and eight female cats were diagnosed with the disease.

Clinical Signs

Box 57-2 summarizes the historical and physical examination abnormalities in dogs with IMHA. The clinical signs associated with IMHA are a reflection of the inflammatory reaction and the resultant anemia. The onset of IMHA can be acute or insidious. Lethargy, depression, and anorexia are the most common signs. Vomiting and diarrhea are reported occasionally. Sudden collapse and syncope are less common signs. The owner may note discolored urine. Most often discoloration is caused by bilirubin content, but occasionally port wine-colored urine is seen, consistent with intravascular hemolysis. The relationship of vaccination to the development of IMHA is controversial. The most common signs in cats with primary IMHA are anorexia and lethargy. Other signs (pica, vomiting, pruritus, dyspnea, epistaxis, polydipsia, and obstipation) are less common (Kohn et al., 2006).

Physical examination findings in dogs include pallor, icterus, depression, and weakness. Tachycardia is present in approximately one third of dogs. Occasionally cardiac murmurs are noted secondary to severe anemia or underlying heart disease. Hepatosplenomegaly can often be noted on abdominal palpation. The hair in the perineal area or around the penis may be discolored by the bilirubin or hemoglobin in the urine. Petechial hemorrhages may be evident in mucous membranes and in the skin of animals that have a concurrent thrombocytopenia or vasculitis. Fever and lymphadenopathy are sometimes present. Cats were reported to have pale and sometimes icteric (2 of 19) mucous membranes, lymphadenopathy, and heart murmurs (Kohn et al., 2006). Respiratory distress in animals with IMHA may be consequent to pulmonary thromboembolism.

Laboratory Results

The typical results of laboratory evaluation in dogs are listed in Table 57-1. Anemia can be moderate to severe. Packed cell volume (PCV) can be as low as 6%. As many as 50% of dogs with IMHA have nonregenerative or poorly regenerative anemia based on reticulocyte index. Eleven of 19 cats with IMHA had anemia categorized as nonregenerative (Kohn et al., 2006). Spherocytosis is a common but nonspecific finding in dogs with IMHA. Spherocytosis implies an underlying immune mechanism but does not indicate whether the etiology is primary or secondary. Spherocytosis may also be hereditary in certain breeds of dogs. Because of small erythrocyte size in cats, spherocytes are difficult to detect. Polychromasia, anisocytosis, and nucleated RBCs are present

Box 57-1

Causes of Hemolytic Anemia in Dogs and Cats**Inherited Causes**

- Pyruvate kinase deficiency
- Phosphofructokinase deficiency
- Chondrodysplasia/anemia
- Nonspherocytic hemolytic anemia

Immune-Mediated Causes (Primary)

- Primary (idiopathic) immune-mediated hemolytic anemia (IMHA)
- IMHA associated with systemic lupus erythematosus
- Neonatal isoerythrolysis
- Incompatible transfusions

Metabolic Causes

- Hypophosphatemia

Neoplastic Causes

- Microangiopathic anemia associated with hemangiosarcoma or lymphoma

Infectious Causes

- *Babesia canis*
- *Babesia gibsoni*
- *Mycoplasma haemominutum*
- *Mycoplasma haemofelis*
- *Mycoplasma haemocanis*
- *Dirofilaria immitis*

on blood smears from dogs with an appropriate regenerative response. Macrocytosis is common in dogs with strongly regenerative anemias. Microscopic autoagglutination is noted in blood smears from some dogs with IMHA.

Leukopenia is uncommon and may result from antibody-mediated neutropenia, sepsis, or decreased bone marrow production. Very high white blood cell counts (up to 100,000/ μl) have been attributed to the inflammatory reaction, cytokines that act as colony-stimulating factors for various cell lines, and general activation of the bone marrow secondary to anemia. One study (McManus and Craig, 2001) found a correlation between leukocytosis in dogs with IMHA and tissue necrosis, specifically centrilobular hepatic necrosis, presumably secondary to hypoxemia. Cats with primary IMHA generally have normal leukocyte counts but can demonstrate a mild leukocytosis.

Thrombocytopenia is a concurrent finding in approximately 70% of dogs and 42% of cats with IMHA. Thrombocytopenia can be a result of immune-mediated platelet destruction or consumptive processes such as sepsis or disseminated intravascular coagulation (DIC).

Autoagglutination is considered the hallmark of class I IMHA and negates the need for direct Coombs' testing. In my retrospective study of 105 cases of canine IMHA, 70 of the 73 dogs tested had blood samples that were positive for autoagglutination. In 19 cats with primary IMHA, all had macroscopic slide agglutination. Erythrocytes coated with high titers of warm antibody and complement can spontaneously agglutinate. To ensure that the agglutination is real autoagglutination and not the result of rouleaux formation, 1 drop of ethylenediaminetetraacetic acid-anticoagulated (EDTA) blood is placed with 1 to 2 drops of saline on a glass microscope slide. The slide is gently rocked to mix the blood and saline, and if agglutination is still present a presumptive diagnosis of IMHA can be made.

There are no consistent serum biochemical abnormalities that aid in the diagnosis of IMHA. Serum biochemical parameters often reflect hemolysis, dehydration, and hypoxic damage to organs. More than two thirds of dogs with IMHA exhibit hyperbilirubinemia. Prerenal azotemia can be noted in patients that are severely affected. Azotemia secondary to acute renal failure is rare but can result from renal ischemia, DIC, sepsis, and hemoglobin (pigment) nephropathy. Mild-to-moderate elevations in serum hepatic transaminases have been attributed to hepatocyte hypoxia. Serum alkaline phosphatase may be increased because of cholestasis from mononuclear phagocyte system hyperplasia or extramedullary hematopoiesis within the liver. Low total carbon dioxide (TCO₂) or serum bicarbonate concentration may reflect probable lactic acidosis associated with decreased tissue oxygen delivery. Hyperglobulinemia is noted occasionally and may be indicative of the inflammatory response. Cats with IMHA have hyperbilirubinemia as the primary biochemical abnormality. Liver enzymes were normal in 9 of 19 cats and were variably increased in the remainder of the cats studied. Six of 19 cats were azotemic.

Bilirubinuria is the most common finding on urinalysis. In dogs with intravascular hemolysis, hemoglobinuria is evident as a dark red color, which persists following centrifugation. Additional abnormalities may include proteinuria, hematuria, and cylinduria. Bacteriuria and pyuria are indicative of concurrent urinary tract infection. Any signs of urinary tract infection warrant further workup because bacterial endocarditis can cause urinary tract infection and a secondary IMHA. The urine is usually concentrated if the dog is dehydrated; however, the urine specific gravity can be isosthenuric if acute or chronic renal failure is present.

Direct Coombs' Test

The direct Coombs' test detects the presence of antibodies and/or complement on the erythrocyte surface. The Coombs' test result is positive in 35% to 60% of dogs with IMHA. False-positive test results can be produced by concurrent disease states such as neoplasia, mycoplasmosis, babesiosis, bacterial infections, administration of certain drugs, previous transfusion, improper antisera preparation, and nonspecific adsorption of serum proteins on damaged RBCs. It is important to interpret the test results in light of the individual patient and realize that a positive test result is consistent with but not diagnostic for IMHA. A positive Coombs' test in cats can occur with feline leukemia virus infection, *Mycoplasma haemofelis* infection, feline infectious peritonitis virus infection, myeloproliferative diseases, other neoplastic diseases, and chronic bacterial infections. A direct-flow cytometric erythrocyte immunofluorescence assay for dogs may be more sensitive and cost effective when it becomes more widely available (Quigley et al., 2001). The authors showed a sensitivity of 92% with flow cytometry compared to 53% for the Coombs' test and a specificity of 100% for both tests.

Additional Diagnostic Tests

Arterial blood gas analysis is indicated in the dyspneic dog. Profound hypoxemia with normocapnia and normal acid-base balance is consistent with pulmonary throm-

boembolism (PTE) (see Chapter 155). The calculated alveolar arterial oxygen gradient is markedly increased in these dogs. Hypoxemia also can be caused by pulmonary edema or pleural effusion consequent to infusion of crystalloids.

Coagulation parameters in dogs and cats with IMHA have been the subject of recent interest. A hypercoagulable state in dogs with IMHA has been suspected and was supported by studies of Mischke (1998). Scott-Moncrieff and associates (2001) prospectively studied 20 dogs with IMHA and showed that the activated partial thromboplastin time (aPTT) was prolonged in nine dogs and the one-stage prothrombin time (OSPT) was prolonged in two dogs. Fibrinogen concentration was increased in 17 dogs, fibrin degradation products were increased in 12 dogs, and D-dimer concentration was increased in 16 dogs. Antithrombin activity was decreased in 10 dogs. Nine dogs (45%) were diagnosed with DIC based on the authors' criteria. Cats with primary IMHA also demonstrate coagulation abnormalities. Three of 10 cats in one study had prolongation of aPTT and OSPT. Two of these cats also had thrombocytopenia.

Bone marrow examination may be useful, especially in cases in which the regenerative response is poor. Evaluation of bone marrow aspirates from the majority of dogs with IMHA shows erythroid or generalized marrow hyperplasia. Erythrophagocytosis is seen occasionally and may be indicative of immune-mediated red cell destruction within the bone marrow. Erythrocyte hypoplasia or erythroid maturation arrest can also be seen, implying targeting of common antigens expressed both on mature RBCs and RBC precursors. The bone marrow in cats with IMHA has been described by Weiss (2006). Bone marrow from these cats was normal-to-hypercellular with predominant changes in the erythroid line, including maturation defects, binucleation, fragmented nuclei, and mild megaloblastosis. There was also an increase in small lymphocytes in the marrow of affected cats.

Imaging of the thorax and abdomen is warranted in some animals with IMHA. Thoracic radiographs aid in ruling out underlying diseases such as neoplasia and infection that may be associated with secondary IMHA. Routine radiography may also detect evidence of PTE in dogs. A pronounced interstitial pattern is most commonly noted; however, a patchy alveolar pattern and pleural effusion can also be seen (Klein, Dow, and Rosychuk, 1989). Other considerations for increased lung density in IMHA patients include secondary bronchopneumonia, congestive heart failure, noncardiogenic pulmonary edema, and circulatory overload from fluid therapy. Hepatosplenomegaly can be detected by abdominal radiography. In addition, evidence of abdominal neoplasia, gastric foreign bodies, or other intraabdominal abnormalities may be detectable by radiography or ultrasonography.

Pulmonary perfusion can be assessed with nuclear scintigraphy in dogs with IMHA and suspected PTE. This modality is the most accurate, although generally unavailable, method of detecting thromboembolism, and carries practical difficulties related to the radiopharmaceutical. Irregular distribution of radiolabeled macroaggregated albumin is consistent with vascular obstruction by thromboemboli.

THERAPY FOR IMMUNE-MEDIATED HEMOLYTIC ANEMIA

The therapy for dogs with IMHA is both supportive and specific for the disease. Supportive care is necessary for patients with severe IMHA such as the intravascular or autoagglutinating forms of the disease. There have been few controlled clinical studies supporting the use of specific therapeutic regimens.

Supportive Care

Supportive care primarily involves maintenance of hydration, acid-base balance, and organ perfusion. In addition, diuresis is indicated in patients with intravascular hemolysis to prevent hemoglobin nephrosis. Although the role of free hemoglobin as a nephrotoxin is controversial, in my experience a significant portion of dogs with intravascular IMHA have clinical laboratory data suggestive of acute renal failure and necropsy evidence of hemoglobin (pigment) nephrosis. Subcutaneous fluid administration may be adequate; however, this route is contraindicated in dogs that are severely thrombocytopenic because of the risk of subcutaneous hemorrhage. Intravenous catheter placement in a peripheral vein is recommended but has been identified as a risk factor for the development of PTE. Jugular vein catheterization may not be advisable because of the potential for coagulopathy, both hemorrhagic and hypercoagulable states. Vigorous volume expansion can lead to pulmonary edema or pleural effusion. Such patients often demonstrate jugular venous distension or pulses. Noncardiogenic pulmonary edema may develop possibly related to injury to the alveolar capillary membrane. Congestive heart failure may be precipitated by acute anemia and crystalloid therapy in dogs or cats with preexistent heart disease.

Attention to aseptic technique and the use of latex gloves when handling patients with IMHA are extremely important. Immunosuppressive therapy increases the risk of sepsis in these patients. Although prophylactic antibiotic therapy is not necessary, routine monitoring for sepsis is mandatory. A dog that is being treated with immunosuppressive doses of glucocorticoids may not be able to generate a fever; thus body temperature is not an accurate means of identifying sepsis.

Dogs should be walked outside to urinate several times daily, if possible, to minimize urine retention and the potential for urinary tract infections. Cages should be well padded to aid in the prevention of decubital ulcers.

Specific treatment may be indicated in patients with vomiting related to IMHA or to the immunosuppressive therapy. Gastrointestinal ulceration may be prevented by the early use of histamine H_2 blockers, proton pump blockers, or prostaglandin analogs. Antiemetics such as metoclopramide may be necessary for controlling vomiting.

Blood Transfusion

Unique risks are associated with transfusions in dogs with IMHA. The presence of autoantibodies in the patient may shorten the survival of the transfused RBC,

reducing the benefit of the transfusion. Transfusion may suppress the erythropoietic response of the patient, prolonging the time to erythroid recovery. Transfusions have been suspected of increasing the risk of PTE in dogs with IMHA (Klein, Dow, and Rosychuk, 1989).

Individual patient selection is important; there is no exact PCV that indicates transfusion. The patient's need for transfusion is determined by evaluation of laboratory parameters and the clinical signs associated with the anemia. Frequent assessment of the PCV is important in determining the trend (up or down) and the rate of the change. Patients undergoing severe, rapid hemolysis should be monitored more frequently. If the PCV is stable, transfusion may not be warranted. Clinical parameters, including patient attitude, exercise tolerance, respiratory rate, and heart rate, may indicate the need for a transfusion. In general, if the dog is stable and comfortable at rest, transfusion is not necessary.

If blood transfusion is indicated, the clinical status of the dog must be taken into consideration in choosing the best blood product for the animal (also see Chapter 56). In general, if the patient has not been typed, blood from universal donors (i.e., DEA 1-7 negative, except DEA 4 can be positive) should be used. If RBCs are the only component needed by the patient, fresh packed RBCs may be given to reduce the risk of transfusion reactions to plasma proteins present in whole blood. The recipient gains the most benefit from a fresh unit. If the dog has a coagulopathy such as DIC in conjunction with anemia, fresh whole blood or packed RBCs and fresh-frozen plasma may be needed. Administration of blood products should be initiated cautiously (0.5 to 1 ml/kg/hour for the first 30 minutes), and the patient monitored closely for signs of transfusion reactions. If no reactions are noted, the rate can be increased so that the full unit is completely administered within the next 4 hours. Blood can be administered at a rate of 20 to 80 ml/kg/hour in life-threatening situations. If the patient has reduced cardiovascular function, transfusion rates should not exceed 4 ml/kg/hour. Hemoglobin solutions (Oxyglobin, Biopure) may also be considered in patients requiring increased oxygen delivery to tissues. Survival rates in one study were not different for dogs with IMHA that received Oxyglobin/blood, blood/Oxyglobin, or Oxyglobin alone (Rentko, Hasndler, and Hanson, 2000).

Immunosuppressive Therapy

Glucocorticoids

Glucocorticoids are the mainstay of therapy in the majority of dogs and cats with IMHA. The major therapeutic effect of glucocorticoids in IMHA is to decrease Fc receptor-mediated RBC destruction within the mononuclear phagocyte system. Glucocorticoids also inhibit complement activation and reduce circulating levels of cytokines, thereby diminishing the amplification of the immune response. Prednisone/prednisolone or prednisolone acetate is recommended at immunosuppressive doses of 2 mg/kg twice daily orally or by injection, respectively. This dosage is maintained until the patient shows clinical improvement (rising PCV) for at least 5 to 7 days. At this point the dosage can be reduced by 25% to 50% every 3 to 4 weeks

if the complete blood count supports the view that remission is maintained. If at any time there is any indication of relapse such as return of autoagglutination or a reduction in PCV, the dose of prednisone is increased to the next higher dose, and future dosage tapering is slowed. In severe relapses initial immunosuppressive doses may need to be reinstituted. When the dose of prednisone is reduced to 0.5 mg/kg/day, alternate-day therapy may be initiated at the next monthly recheck evaluation if remission has been maintained. Although no clinical trials have been completed to assess the need for lifelong therapy, relapse of IMHA does occur.

Cytotoxic Drugs

In severe cases of IMHA (intravascular or autoagglutinating) or in cases unresponsive to glucocorticoids alone, the addition of cytotoxic or immunosuppressive drugs may be necessary (see Chapter 55 for more information regarding immunosuppressive drugs). Cyclophosphamide and azathioprine have been used individually or together in these situations.

Azathioprine. The recommended dose of azathioprine (Imuran, Glaxo Wellcome) is 2 mg/kg given daily or on alternate days. I use azathioprine daily for 4 days and then on alternate days. When the prednisone dose is reduced to alternate-day administration, azathioprine can be given on the days when prednisone is not given. If after 4 weeks remission is maintained, the azathioprine can be discontinued. In dogs that are sensitive to the side effects of glucocorticoids, azathioprine can be used on alternate days to maintain remission. The side effects of azathioprine include gastrointestinal upset, bone marrow suppression, poor hair growth, and pancreatitis. The study of Mason and colleagues (2003) demonstrated no benefit to combination cyclophosphamide-prednisone therapy when compared to simple prednisone therapy in the treatment of extravascular IMHA.

Cyclosporine A. Cyclosporine A (CsA, Neoral, Sandoz Pharmaceuticals) is a potent immunosuppressive drug directed at cell-mediated immune responses. CsA blocks the expression of the interleukin-2 and interferon- γ genes within T lymphocytes, thereby blocking the amplification of the immune response at a crucial step in T-cell activation. It has been used effectively alone or in combination with other immunosuppressive therapies in dogs with IMHA. Because of variability in gastrointestinal absorption, predictable blood levels are difficult to attain, necessitating the determination of serum drug concentrations for accurate dosing. In dogs the most common side effects include vomiting, diarrhea, and anorexia. Therapy with CsA is initiated at a dosage of 5 mg/kg PO every 12 to 24 hours. Ideally therapeutic drug monitoring is recommended at 2- to 4-week intervals. A trough concentration of 100 to 300 ng/ml as measured by high-performance liquid chromatography is recommended (Vaden et al., 1995).

Mycophenolate Mofetil. Mycophenolate mofetil (CellCept, Roche Pharmaceuticals) is an immunosuppressive medication that has been used to treat myasthenia gravis, another immune-mediated disease in dogs. Mycophenolate mofetil is converted to mycophenolic acid, which inhibits purine synthesis primarily in B and T lymphocytes,

thus reducing autoantibody production. Mycophenolate mofetil is used at a dosage of 10 to 20 mg/kg every 12 hours orally. Side effects are minimal and are usually nausea, vomiting, or diarrhea. In refractory cases of IMHA in dogs, mycophenolate mofetil is used to aid in inducing remission and then may be discontinued. Studies need to be completed to identify the role of mycophenolate mofetil in the treatment of IMHA.

Intravenous γ -Globulin

Intravenous γ -globulin (IVGG) administration has been used to treat several immune-mediated diseases in people, specifically IMHA, immune-mediated thrombocytopenia, and immune-mediated neutropenia. The mechanism by which IVGG suppresses the immune destruction of RBCs is thought to be blockade of macrophage Fc receptors and possibly antiidiotypic down-regulation of autoantibody production. When given at a dose of 1 g/kg intravenously over 6 to 12 hours, a profound reticulocytosis occurs, followed by a more slowly rising PCV. In a recent study of IVGG in dogs with IMHA, 8 of 11 dogs survived and attained a remission, although long-term follow-up data were not available (White et al., 2003). No adverse side effects of IVGG treatment were noted.

Liposome-Encapsulated Clodronate

The use of liposome-encapsulated clodronate (dichloromethylene diphosphonate) to deplete splenic macrophages and block clearance of Ig-coated RBCs has been evaluated in a mouse model of IMHA and more recently in dogs with IMHA (Mathes, Jordan, and Dow, 2006). It appears to be well tolerated in dogs, and preliminary evidence suggests its ability to rapidly block the clearance of opsonized RBCs in normal dogs and dogs with IMHA, resulting in improved survival.

COMPLICATIONS OF IMMUNE-MEDIATED HEMOLYTIC ANEMIA IN DOGS

Complications of IMHA can be severe and life threatening. They include refractory anemia, hemorrhage, bacterial or fungal infections, acute renal failure, and PTE. It is difficult to glean from the literature the proportion of dogs that die from specific causes. In my retrospective study at a referral institution 40% of the dogs with IMHA responded to treatment and survived. Sixty percent died or were euthanized because of refractory anemia, relapse of anemia, or other complications of the disease or its treatment. The cause of death as determined by necropsy was available in 25 dogs. Three dogs with intravascular hemolysis had evidence of acute renal failure secondary to hemoglobin nephrosis. One dog died of sepsis. PTE was found in 22 dogs.

Refractory anemia is common in dogs with IMHA. Failure of the dog to respond to immunosuppressive agents often leads to death or euthanasia.

Complications of IMHA also include hemorrhage, which may result from the disease itself or its treatment. Gastrointestinal hemorrhage is commonly seen and can

result from the combined effects of ischemia, thrombocytopenia, DIC, and drug-associated alterations in epithelial cell turnover and gastric acid and mucus production.

Therapy for IMHA is still crude and nonspecific. Unfortunately immunosuppressive drugs inhibit not only aberrant immune responses but also immune responses necessary to protect the host from infection. Disseminated bacterial, fungal, and protozoal infections have contributed to the deaths of dogs with IMHA.

PTE is a common cause of death in dogs with IMHA. In a study by Klein, Dow, and Rosychuk (1989), 32% of 31 dogs with IMHA died of PTE based on findings at necropsy. The authors postulated that hypercoagulability is most probably responsible for thrombus formation. Potential causes of hypercoagulability may include an imbalance in procoagulant and naturally occurring anticoagulant factors, DIC, endothelial cell-mediated coagulation triggered by antierythrocyte antibodies, and procoagulant factors released from damaged erythrocytes. Hyperbilirubinemia, hypoalbuminemia, intravenous catheter placement, and severe thrombocytopenia ($<50,000/\mu\text{L}$) have been identified as risk factors for the development of PTE (Klein et al., 1989; Carr, Panciera, and Kidd, 2002). The clinical signs of acute dyspnea, orthopnea, and profound anorexia should prompt further evaluation (Chapter 155). Sudden death without prior clinical signs also occurs.

Prophylactic therapy to prevent thrombosis has been recommended in dogs with IMHA. As stated previously, DIC is common in dogs with IMHA. Plasma has been used to treat DIC initiated by other disorders such as sepsis, but plasma did not decrease mortality of dogs with IMHA and PTE in one study (Thompson, Scott-Moncrieff, and Brooks, 2004). Heparin has not consistently prevented the development of PTE. Two recent studies of heparin in dogs with IMHA failed to show a benefit on survival (Fryer, McMichael, and Slater, 2005; Breuhl, Scott-Moncrieff, and Brooks, 2005). In one of these studies doses of up to 300 units of unfractionated heparin per kilogram every 6 hours were not successful in attaining target anti-Xa activity. The addition of aspirin at a dose of 1 to 2 mg/kg every 24 hours may be of benefit. A study of aspirin in dogs with IMHA showed a significantly improved survival rate in dogs receiving azathioprine and aspirin in conjunction with glucocorticoids compared to those receiving azathioprine and glucocorticoids or azathioprine, heparin, and glucocorticoids (Weinkle et al., 2005). Until the underlying mechanisms promoting thrombus formation are identified, it is unlikely that an effective antithrombotic protocol will be developed.

CHAPTER 58

Nonregenerative Anemias

DOUGLAS J. WEISS, *St. Paul, Minnesota*

EVALUATION OF NONREGENERATIVE ANEMIAS

Nonregenerative anemias are caused by a broad spectrum of primary and secondary disease processes that must be differentiated before determining a prognosis or instituting a therapeutic plan. A diagnostic plan for evaluation of anemic disorders is outlined in Box 58-1. Initial evaluation should include a careful history to exclude drug or toxin exposure that may have caused the hematologic dyscrasia. In addition, immune-mediated and infectious causes of anemia should be evaluated with appropriate diagnostic testing (see Chapter 57). Mild-to-moderate nonregenerative anemias frequently occur secondary to inflammatory neoplastic, renal, hepatic, and certain endocrine disorders. Appropriate testing should be performed to detect these conditions. Once this initial evaluation has been completed, bone marrow aspiration cytology and core biopsy are indicated. The combination of bone marrow aspiration cytology and core biopsy is essential to fully evaluate both cytologic details and histopathologic alterations.

DRUG-INDUCED HEMATOLOGIC DYSCRASIAS

A growing number of drugs are associated with hematologic disorders in animals. Some drugs, most notably chemotherapeutic agents, consistently cause hematologic disorders at or near the therapeutic doses. Other drugs induce idiosyncratic hematologic dyscrasias. The most frequent types of idiosyncratic drug reactions are immune-mediated hematologic reactions and toxic injury to bone marrow. Drugs most frequently reported to induce hematologic dyscrasias include chemotherapeutic agents, estrogenic compounds (dogs), phenylbutazone, acetaminophen, aspirin, trimethoprim/sulfadiazine, phenobarbital (dogs), propylthiouracil (cats), methimazole (cats), and griseofulvin. Other drugs associated with hematologic dyscrasias include cephalosporins, carprofen, meclizolam, chloramphenicol, primidone, phenytoin, metronidazole, levamisole, albendazole, fenbendazole, thiacetarsamide, amiodarone, captopril, quinidine, colchicine, and mitotane.

HEMATOLOGIC DISORDERS SECONDARY TO OTHER DISEASE PROCESSES

Inflammatory diseases are consistently accompanied by a mild-to-moderate normocytic, normochromic, nonregenerative anemia, a condition termed *anemia of inflammatory disease (AID)*. The hematocrit drops within the first

few days after onset of inflammation and then stabilizes. Hematologic alterations also commonly accompany large or metastatic malignancy. Disseminated malignancy is generally accompanied by AID, although acute or chronic blood loss also may be involved. Chronic blood loss can cause an iron deficiency that further impairs erythropoiesis. Microangiopathic hemolytic anemia can result from damage to vascular endothelium or from fibrin deposition within the vessels. The hallmark of this process is the presence of schistocytes and keratocytes in the blood of affected animals. In most animals with AID or anemia of malignancy, the anemia is mild and does not require treatment. The anemia usually resolves with successful treatment of the underlying disease and usually responds to erythropoietin (EPO) therapy.

Chronic renal disease/renal failure consistently results in normocytic, normochromic, nonregenerative anemia. The anemia, although complex, is primarily the result of decreased EPO production by the kidney and is responsive to EPO replacement therapy. Alternatively some dogs and cats with late-stage renal failure develop pancytopenia associated with an aplastic bone marrow.

INFECTIOUS DISEASES

Ehrlichia and *Anaplasma* Infections

Acute monocytic and granulocytic ehrlichiosis are well-recognized disease conditions in dogs but have also been identified in cats. In dogs thrombocytopenia is the most consistent hematologic alteration. Although dogs with granulocytic ehrlichiosis readily respond to doxycycline therapy, dogs with monocytic ehrlichiosis frequently develop subclinical and chronic phases of the disease after an initial response to doxycycline. In chronic canine monocytic ehrlichiosis, pancytopenia is the result of decreased bone marrow production. In feline monocytic ehrlichiosis, nonregenerative anemia is a consistent finding, with neutropenia and thrombocytopenia present in some cats. Because some *ehrlichia*-infected cats test positive for antinuclear antibodies, feline ehrlichiosis can be confused with immune-mediated disease processes. A polymerase chain reaction test is available for detection of ehrlichiosis.

Parvovirus Infection

Parvovirus invades and destroys rapidly proliferating intestinal epithelium and bone marrow precursor cells in dog and cats. This results in diarrhea and panleukopenia. Bone marrow injury can also occur secondary to septicemia or

Box 58-1

Diagnostic Approach to Evaluation of Nonregenerative Anemias and Multiple Cytopenias**Initial Evaluation**

- A. Establish the presence and severity of anemia
 - 1. Complete blood count
 - 2. Blood smear examination
 - 3. Reticulocyte count
- B. Evaluate history for drug-induced hematologic disorders
- C. Test for diseases causing secondary suppression of erythropoiesis
 - 1. Infectious/inflammatory diseases
 - 2. Neoplasia
 - 3. Chronic renal disease
 - 4. Chronic liver disease
 - 5. Hypothyroidism
 - 6. Hypoadrenocorticism
- D. Test for infectious diseases
 - 1. *Ehrlichia*
 - 2. *Anaplasma phagocytophilum*
 - 3. *Parvovirus*
 - 4. Feline leukemia virus
 - 5. Feline immunodeficiency virus
- E. Test for immune-mediated diseases
 - 1. Direct Coombs' test
 - 2. Antinuclear antibody test

Secondary Evaluation

- A. Bone marrow aspirate and core biopsy
 - 1. Nonregenerative immune-mediated anemia
 - a. Erythroid hyperplasia
 - b. Maturation arrest
 - c. Pure red cell aplasia
 - 2. Aplastic anemia
 - a. Infectious (*Ehrlichia*, *Parvovirus*, feline leukemia virus)
 - b. Drugs
 - c. Chronic renal failure
 - d. Idiopathic
 - 3. Myelonecrosis
 - 4. Myelofibrosis
 - 5. Inflammation
 - a. Acute
 - b. Pyogranulomatous
 - c. Granulomatous
 - 6. Hemophagocytic syndrome
 - 7. Dysmyelopoiesis

MDS-EB, MDSs with excess myeloblasts; MDS-RC, MDSs with refractory cytopenias; MDS-SD, MDSs with sideroblastic differentiation

endotoxemia. The bone marrow is characterized by severe degenerative changes in hematopoietic precursor cells, multifocal areas of necrosis, and many phagocytic macrophages. Broad-spectrum antibiotic therapy and supportive care is essential to recovery. Hematologic recovery is usually rapid if the animals survive the secondary bacterial infection.

Feline Leukemia Virus Infection

In cats infected with feline leukemia virus (FeLV), anemia and granulocytopenia frequently develop early and predispose to bacterial infections. The anemia is frequently macrocytic and nonregenerative. Either thrombocytosis with increased mean platelet volume or thrombocytopenia can be seen. Bone marrow of infected cats is characterized by granulocyte hypoplasia or by a maturation arrest at the myelocyte or metamyelocyte stage. Other hematologic dyscrasias that have been documented in FeLV-infected cats include hemolytic anemia, pure red cell aplasia (PRCA), aplastic anemia, and myelofibrosis.

Feline Immunodeficiency Virus Infection

Feline immunodeficiency virus (FIV)-infected cats have transient neutropenia and persistent lymphopenia. Thrombocytopenia is a less frequent finding. Bone marrow alterations in symptomatic cats include granulocyte and erythroid hyperplasia and dysplastic changes in erythroid

and megakaryocyte cell lines. When coinfecting with FeLV, FIV-infected cats are frequently anemic and leukopenic.

NONREGENERATIVE IMMUNE-MEDIATED ANEMIAS/PURE RED CELL APLASIA

Several studies indicate that a high percentage of dogs and cats with immune-mediated hemolytic anemia (IMHA) have a nonregenerative anemia when initially diagnosed. Associated bone marrow changes include erythroid hyperplasia with few polychromatophilic erythrocytes, erythroid maturation arrest, or PRCA. In addition, dysmyelopoiesis, myelofibrosis, myelonecrosis, and acute inflammation may be present. Plasma cell hyperplasia is a consistent finding in dog bone marrow, and lymphocytosis is a frequent finding in cat bone marrow.

Diagnosis of IMHA can be problematic. If the diagnosis is restricted to a positive direct Coombs' test or autoagglutination (or spherocytosis in dogs), some cases of IMHA will be missed. Therefore IMHA sometimes becomes a diagnosis of exclusion. Differential diagnosis in cats includes FeLV and FIV infections, feline infectious peritonitis, feline infectious anemia, hemolytic drugs/toxins, and myelodysplastic syndromes. In dogs ehrlichiosis, babesiosis, leishmaniasis, and hemolytic drugs/toxins should be excluded. Immune-mediated hemolytic anemia also can develop as a secondary condition. Associated disorders include lymphoma, a variety of drug treatments and vaccinations, ehrlichiosis, and bee stings.

PRCA is defined as the presence of a severe nonregenerative, normocytic, normochromic anemia and a marked erythroid hypoplasia in bone marrow. Total leukocyte and platelet counts are within or above reference intervals. It occurs in both dogs and cats and is thought to result from an immune response that attacks early erythroid precursor cells in the bone marrow. However, in cats PRCA also can be caused by FeLV subgroup C infection. Although affected dogs tend to be middle aged, cats tend to be younger. In cats the percentage of lymphocytes in bone marrow is invariably increased, and a slight lymphocytosis may be present in the blood.

The approach to treatment of nonregenerative IMHA and PRCA is similar to that of regenerative IMHA, and in my experience the response rate is similar. Prednisone (2.2-4.4 mg/kg q24h orally [PO] as a single or divided dose) has been the mainstay in treatment of IMHA. Because of the high rate of thromboembolism and evidence of circulating activated platelets in dogs, ultralow-dose aspirin (0.5 mg/kg q24h PO) is recommended for all patients. Concurrent azathioprine therapy (2 mg/kg q24h PO tapering to 0.5 to 1 mg/kg q48h) has resulted in improved survival times (see Chapters 19 and 20).

APLASTIC ANEMIA

Aplastic anemia is defined as the presence of a bicytopenia or pancytopenia in the blood and a marrow in which more than 95% of the hematopoietic space is occupied by adipose tissue. Causes of aplastic anemia in dogs include infectious agents (*Ehrlichia canis*, *Parvovirus*) drug toxicities (estrogen, phenylbutazone, trimethoprim-sulfadiazine, quinidine, chemotherapeutic agents, thiactarsemide, albendazole, captopril, griseofulvin), ionizing radiation, and idiopathic causes. Dogs with idiopathic aplastic anemia are usually less than 3 years old. The anemia is moderate to severe, and neutropenia and thrombocytopenia are usually severe. Although the prognosis for idiopathic aplastic anemia is guarded to poor, some dogs do recover with supportive care. No specific therapy short of bone marrow transplantation is available at this time.

Disease conditions associated with aplastic anemia in cats include chronic renal failure, FeLV infection, and methimazole and griseofulvin toxicities. Idiopathic aplastic anemia also occurs in cats. In some cats starvation may play a role in the development of marrow aplasia.

MYELONECROSIS

Myelonecrosis in the dog consists of focal or multifocal areas of coagulative necrosis or individual cell necrosis. In cats individual cell necrosis is seen, but coagulative necrosis is rarely seen. Chronic necrosis is frequently accompanied by variable degrees of myelofibrosis. Associated disease conditions in dogs include sepsis, lymphoma, IMHA, and systemic lupus erythematosus. Drug treatments associated with bone marrow necrosis include phenobarbital, carprofen, metronidazole, mitotane, cyclophosphamide, vincristine, colchicine, and fenbendazole. Although there is no specific treatment for canine myelonecrosis, the prognosis appears to be quite good, with complete hematologic recovery seen in most cases. Diseases associated with

myelonecrosis in cats include nonregenerative IMHA, FeLV infection, myelodysplastic syndromes, and acute leukemia. The prognosis for myelonecrosis in cats depends on the associated disease process.

SECONDARY MYELOFIBROSIS

Myelofibrosis is defined as proliferation of fibroblasts, collagen, or reticulin fibers in bone marrow. Myelofibrosis (i.e., secondary myelofibrosis) occurs most frequently secondary to bone marrow injury. Therefore it is a frequent sequela of myelonecrosis. Myelofibrosis also occurs as a rare chronic myeloproliferative condition termed *idiopathic myelofibrosis*. In dogs secondary myelofibrosis is associated with IMHA; neoplasia; and drug treatments, including phenobarbital, phenytoin, phenylbutazone, and colchicine. Diseases associated with secondary myelofibrosis in cats include IMHA, myelodysplastic syndromes, acute myelogenous leukemia and chronic renal failure. The most frequent hematologic finding in both dogs and cats is moderate-to-severe nonregenerative anemia, with relatively few animals being neutropenic or thrombocytopenic. Other frequent blood findings in dogs included ovalocytosis, dacryocytosis, and metarubricytosis. No specific treatment for myelofibrosis is available. Although the prognosis for secondary myelofibrosis is guarded, approximately half of affected dogs recover.

INFLAMMATION

Acute, pyogranulomatous, and granulomatous inflammation has been documented in bone marrow. Acute inflammatory lesions have been associated with nonregenerative IMHA, bacterial sepsis, and feline infectious peritonitis. Some affected dogs have a history of acute onset of lameness or bone pain. Neutrophilia, left shift, and toxic change may be seen in the blood. Bone marrow core biopsies are characterized by dilation of sinusoids, fibrin deposits, multifocal accumulations of neutrophils, and necrosis. Affected dogs and cats tend to have moderate-to-severe anemia. Pyogranulomatous inflammation has been observed in dogs and cats with disseminated histoplasmosis, and anemia may be quite prominent in some animals. Granulomatous inflammation has been seen in dogs with systemic fungal infections. Approach to treatment of inflammatory bone marrow disorders is based on treatment of the associated disease condition.

HEMOPHAGOCYTIC SYNDROME

Hemophagocytic syndrome is a benign proliferative disorder of macrophages and must be differentiated from a malignant proliferation of histiocytes (i.e., malignant histiocytosis). Criteria for diagnosis of hemophagocytic syndrome include the presence of bicytopenia or pancytopenia in the blood and greater than 2% hemophagocytic macrophages in bone marrow. Cases that have concurrent myelonecrosis, myelofibrosis, or marrow inflammation should be excluded because the hemophagocytic macrophages are probably the result of these conditions and not a primary disorder. Disease conditions associated with hemophagocytic syndrome in dogs include IMHA, systemic lupus erythematosus,

sepsis, *E. canis* infection, blastomycosis, lymphoma, and myelodysplastic syndromes. Approximately 20% of canine cases are idiopathic. These cases are characterized by acute onset of weakness, lethargy, fever, and splenomegaly.

Survival appears to depend on the associated disease condition. Records from the University of Minnesota Veterinary Medical Center indicate that nine of nine dogs with immune-associated hemophagocytic syndrome died within 1 month, whereas four of five dogs with infection-associated hemophagocytic syndrome survived. Therapy of hemophagocytic syndrome should be directed at treating associated disease conditions and administering immunosuppressive doses of prednisone (2.2 to 4.4 mg/kg q24h PO as a single or divided dose) to suppress macrophage activity.

DYSMYELOPOIESIS

Dysmyelopoiesis is defined as a hematologic disorder characterized by the presence of morphologic abnormalities (i.e., dysplasia) in one or more hematologic cell line in the blood or bone marrow. Dysmyelopoiesis has been classified in several ways but has most recently been divided into myelodysplastic syndromes (MDSs), secondary dysmyelopoiesis, and congenital dysmyelopoiesis.

Myelodysplastic Syndromes

MDSs are acquired clonal proliferative disorders that are thought to result from a genetic mutation in hematopoietic stem cells. Differentiating an MDS from acute leukemia is based on the percentage of myeloblasts in the bone marrow. Historically leukemias were defined as more than 30% myeloblasts, and MDS as fewer than 30% myeloblasts. More recently some pathologists prefer to use 20% as the cutoff. Myelodysplastic syndromes have been divided into two major categories: MDS with refractory cytopenias (MDS-RC) and MDS with excess myeloblasts (MDS-EB); and one minor category, MDS with sideroblastic differentiation (MDS-SD). In both dogs and cats MDS-RC and MDS-EB are differentiated based on the percentage of myeloblasts in the bone marrow. MDS-RC has less than 6% myeloblasts, whereas MDS-EB has 6% to 30% myeloblasts.

Hematologic alterations in dogs with MDS-RC consist of moderate-to-severe normocytic, normochromic, nonregenerative anemia. Dysplastic features in bone marrow are usually restricted to the erythroid series. Alternatively cats with MDS-RC have a macrocytic normochromic anemia, and many are pancytopenic. The presence of metarubricytosis and autoagglutination is a frequent finding in blood smears of cat, making it easy to confuse MDS-RC with IMHA. Unlike dogs, dysplasia is seen frequently in all cell lines in the bone marrow of cats. Both dogs and cats with MDS-RC tend to be less severely ill when initially evaluated, tend to have substantially better response to supportive therapy, and have much longer survival times when compared to MDS-EB. The anemia in dogs with MDS-RC is frequently responsive to EPO therapy (50 to 2000 units/kg subcutaneously three times/week).

Dogs and cats with MDS-EB have bicytopenia or pancytopenia. Bone marrow has dysplastic features in all cell

lines, and 6% to 30% myeloblasts are present. Survival for both dogs and cats is short. Treatment is mostly supportive. EPO and other hematopoietic growth factors have been used, but they do not appear to prolong survival. Chemotherapeutic agents, including hydroxyurea, low-dose cytosine arabinoside, and low-dose aclarubicin have been tried with limited success.

MDS-SD is seen infrequently in dogs and cats. It is characterized by a microcytic or hypochromic nonregenerative anemia with siderocytes or sideroblasts in the blood and ringed sideroblasts in bone marrow. Because of the microcytic and hypochromic nature of the anemia, MDS-SD can be confused with chronic iron deficiency anemia.

Secondary Dysmyelopoiesis

Secondary dysmyelopoiesis is associated with a variety of hematologic disorders and drug treatments. Secondary dysmyelopoiesis in dogs has been associated with IMHA, immune-mediated thrombocytopenia, lymphoma, myelofibrosis, and multiple myeloma. Drugs that have been associated with dysmyelopoiesis in dogs include chemotherapeutic agents, estrogen, cephalosporins, chloramphenicol, phenobarbital, and colchicine. Secondary dysmyelopoiesis in cats has been associated with IMHA, immune-mediated thrombocytopenia, lymphoma, and chemotherapy. Cytologic features of MDS and secondary dyserythropoiesis are difficult to differentiate. Features that can be used to differentiate the two disorders include the presence of increased numbers of myeloblasts or rubriblasts in bone marrow in most animals with MDS and the presence of associated disease conditions in secondary dysmyelopoiesis.

BONE MARROW NEOPLASIA

Leukemia

Most dogs and cats with acute and chronic leukemias have a nonregenerative anemia at the time of diagnosis, and some are thrombocytopenic. If leukemic cells extensively displace normal hematopoietic cells in the bone marrow (myelophthisis), pancytopenia can develop. Approximately half of the acute leukemias diagnosed at the University of Minnesota are "aleukemic" (e.g., do not have circulating atypical cells); therefore bone marrow evaluation is critical to establish a diagnosis. Alternatively chronic leukemias usually have moderate-to-marked leukocytosis at the time of diagnosis.

Lymphoma

Unlike in cats, lymphoma is the most frequently diagnosed neoplastic condition in canine bone marrow. Disseminated lymphoma must be differentiated from acute lymphoblastic leukemia. This distinction is based on identification of lymphoblasts in multiple lymph nodes or organs, relatively low numbers of lymphoblasts in the blood, and lack of severe cytopenias. The most consistent hematologic finding in disseminated lymphosarcoma is a mild-to-moderate nonregenerative anemia (see Chapter 72).

Multiple Myeloma

Multiple myeloma is the second most frequently diagnosed neoplastic condition in the bone marrow of dogs and cats. Diagnosis of multiple myeloma depends on finding large numbers of atypical plasma cells in bone marrow with or without the presence of hypercalcemia, osteolytic lesions, a monoclonal gammopathy, or light-chain proteinuria. Features most helpful in differentiating malignant plasma cells from reactive plasma cell hyperplasia include anisocytosis, anisokaryosis, high nuclear-to-cytoplasmic ratio, binucleation, and clustering of plasma cells. These anaplastic features are important in differentiating multiple myeloma from plasma cell hyperplasia associated with immune-mediated diseases, ehrlichiosis, and feline infectious peritonitis infection. Dogs and cats with multiple myeloma frequently have a nonregenerative anemia and may be concurrently thrombocytopenic or neutropenic.

Malignant Histiocytosis

Malignant histiocytosis (MH) appears to occur relatively frequently in dogs with distinct breed predilections, but is diagnosed infrequently in cats. Organs frequently involved include the liver, spleen, lungs, and bone marrow. Affected dogs can have multiple cytopenias, whereas cats may only be anemic. Both dogs and cats have large

numbers of histiocytic cells in bone marrow, but features of malignancy are variable. Features of MH that are useful in differentiating it from hemophagocytic syndrome include greater than 30% histiocytic cells in bone marrow, high nuclear-to-cytoplasmic ratio, and multinuclearity. In addition, MH is rarely confined to the bone marrow. At present disease progression is usually rapid, and disease outcome is invariably fatal (see Chapter 75).

von Willebrand's Disease and Other Hereditary Coagulopathies

ANTHONY P. CARR, *Saskatoon, Saskatchewan, Canada*

BELLE M. NIBBLETT, *Saskatoon, Saskatchewan, Canada*

DAVID L. PANCIERA, *Blacksburg, Virginia*

A number of bleeding disorders demonstrate a genetic basis. The inheritance patterns of hereditary bleeding disorders have been a focus of much attention, but in many instances the genetic basis in dogs and cats is still unknown. However, a variety of genetic tests have recently become available, and these assessments promise to increase accuracy of diagnosis and also reduce the frequency of some of hereditary bleeding disorders. Genetic testing is especially attractive since it often can determine if a dog is affected, a carrier, or free of the offending gene. In contrast, when factor assays are used to determine disease status, the distinction between carrier and free individuals is often difficult. However, even genetic testing will be unable to diagnose all canine and feline bleeding disorders since new mutations can arise. In some cases different mutations are responsible for the same bleeding disorder. Thrombocytopenia, disseminated intravascular coagulation, and platelet function disorders are also discussed in the following three chapters.

VON WILLEBRAND'S DISEASE

von Willebrand's disease (vWD) is the most common inherited bleeding disorder in dogs. It is caused by a lack of von Willebrand's factor (vWF). vWF is an adhesive glycoprotein that is produced by endothelial cells and megakaryocytes. Unlike platelets in other species, canine platelets do not contain large amounts of vWF in their α -granules. Extracellular vWF is found in the subendothelium and circulating in plasma in multimeric form. The multimers vary in size from 0.5 to 20 million daltons (D), with the larger multimers being more hemostatically active. The multimers are composed of identical 270,000-D subunits joined by disulfide bonds.

The predominant function of vWF is to promote the adhesion of platelets to exposed subendothelium, especially in areas of high shear stress. vWF is produced by the endothelium, with 95% secreted constitutively and the other 5% stored in Weibel-Palade bodies (as well as a small amount in platelets). The predominant function of vWF is to promote the adhesion of platelets to exposed subendothelium via binding to the glycoprotein (GP)Ib α -receptor

on platelets. This is especially vital in areas of high shear stress such as arteries. vWF also plays a role in platelet-to-platelet aggregation in conjunction with the GPIIb/IIIa complex (integrin α IIb β 3) and fibrinogen. The other major function of vWF is to form a tightly bound complex with factor VIII, thereby prolonging the half-life of factor VIII, although this is of lesser importance in dogs.

Three types of vWD occur in dogs. In type I vWD all multimers are present but in considerably reduced quantity. This form of vWD is most common. It has been identified in more than 50 breeds of dogs. Breeds associated with type I vWD and a hemorrhagic tendency include the Doberman pinscher, standard poodle, Shetland sheepdog, and German shepherd. The hemorrhagic tendency, although variable, often manifests as increased bleeding associated with surgical procedures or after trauma. Spontaneous mucosal bleeding (epistaxis, urogenital bleeding) can be seen occasionally. Other stressors that suppress hemostasis, such as the transient thrombocytopenia noted to occur after vaccination with a modified-live vaccine or the administration of nonsteroidal antiinflammatory agents that inhibit platelet activity can precipitate bleeding. In severely affected animals spontaneous hemorrhage may be seen and can be protracted. In some dogs decreased vWF has been documented, but a bleeding tendency does not seem to exist. Type I vWD probably represents a heterogeneous group of diseases with marked breed variation. In type II vWD the larger, more effective multimers are absent, and bleeding can be severe. This form of the disease has been identified in German shorthaired and German wirehaired pointers. The most severe form of vWD is type III, in which all multimers are absent. This form of the disease is associated with life-threatening hemorrhagic episodes. It has been reported to occur in Scottish terriers, Chesapeake Bay retrievers, Dutch kooikers, and Shetland sheepdogs.

The mode of inheritance of vWD remains largely unknown, although some of the mutations leading to the disease are recognized. Type I vWD can occur through a large number of defects that typically involve a substitution or deletion of a single nucleotide, resulting in abnormal splicing or a frame shift. This mutation can be autosomal recessive or autosomal dominant, possibly depending on the

amount of incorrect splicing that occurs. Males and females are equally affected. Expression of type I vWD is complex in Doberman pinchers and may or may not be related to homozygosity or heterozygosity of the mutation, but it is not explained by a simple autosomal-recessive inheritance pattern (Brooks, Erb, and Foureman, 2001). It has been proposed that the disease in Doberman pinschers may be produced by a single gene defect (Moser, Meyers, and Russon, 1996), with each allele being responsible for 50% of the vWF level the dog has. A defective allele would result in less than 15% of normal vWF production. The mutation leading to type II vWD is unknown. Inheritance of type III vWD is autosomal recessive and results when the mutation results in a severe change in the intended protein. Variable expression of vWD is related to heterozygosity, inheritance of dominant negative mutations, and other inherited and noninherited extragenic influences (i.e., posttranslational modification) and physiologic factors.

Diagnostic Testing

Determination of vWF levels still remains central to diagnosis of vWD; although, with the sequencing of the canine vWF gene, the underlying genetic abnormalities associated with vWD have been determined for certain breeds of dogs. The validity of many of these assays has not yet been published, and test results should not be interpreted without vWF levels. The deoxyribonucleic acid analysis has the advantage of allowing improved detection of carriers. However, without simultaneously measuring vWF there is risk of false negatives as the individual may have a different mutation leading to vWD than the one that is currently being tested. An individual may have a unique mutation, or there may be multiple mutations leading to disease in certain breeds.

When vWF is analyzed, the patient's vWF is reported as a percentage of a control canine pool. The pool is considered to represent 100%, often expressed as 100 units. Blood for analysis should be anticoagulated with citrate at a 9:1 ratio of blood to anticoagulant or with 15% ethylenediaminetetraacetic acid at a ratio of 1:100. Hemolyzed samples are not to be used since hemolysis causes a significant decrease in vWF levels (Moser et al., 1996). The blood is centrifuged immediately and is then frozen for storage before analysis. The sample should be shipped frozen on dry ice to prevent thawing. In the process of thawing, some proteolysis may occur. This breakdown of protein would tend to elevate vWF artificially when an antigenic assay is used because breaking up large multimers into smaller subunits exposes more antigenic sites (Stokol and Parry, 1995).

Testing of vWF is usually by means of an enzyme-linked immunosorbent assay (ELISA) with the concentration expressed as vWF:antigen (Ag). Using an ELISA, workers at the Comparative Hematology Laboratory at Cornell University established the following ranges: normal range, 70% to 180% vWF:Ag; borderline range, 50% to 69% vWF:Ag; abnormal range, 0% to 49% vWF:Ag (Brooks, 1992). These assays do not determine biologic activity or multimeric distribution. When this system is used, dogs in the normal range are considered free from vWD and are unlikely to transmit the disease. Dogs in the abnormal range are diagnosed as carriers of vWD and can transmit

the trait to offspring. Results can be ambiguous, and dogs in the borderline range cannot be classified definitively. Daily variation in vWF:Ag concentration can be high; thus multiple measurements may be necessary to establish the von Willebrand status of a dog. In cases in which vWF is in the normal range but unexplained bleeding is occurring, electrophoresis can be useful to diagnose type II vWD.

Multimeric distribution can be determined with the use of electrophoresis. This modality is of value in that the larger multimers are thought to be more hemostatically active. It is also possible to measure functional capacity of vWF using vWF collagen-binding activity. Bleeding times can be measured in patients to determine whether a defect of primary hemostasis is present. Both the cuticle bleeding time (CBT; duration of hemorrhage from a toenail that is cut short enough to bleed) and the buccal mucosal bleeding time (BMBT) are prolonged in vWD. The BMBT is the preferred test since the CBT is also prolonged in coagulopathies such as hemophilia A and B. The BMBT is measured by determining the duration of hemorrhage from small standardized cuts in the upper lip (Johnson, Turrentine, and Kraus, 1988). Normal dogs have a BMBT of less than 4 minutes. When one evaluates BMBT results, it is important to remember that BMBT is a global test of primary hemostasis. Not only vWD, but also thrombocytopenia, platelet function defects, and vasculitis result in a prolonged BMBT. The accuracy of BMBT is limited by the finding of up to a 2-minute interobserver and intraobserver variability in test results (Sato, Anderson, and Parry, 2000).

Physiologic Factors Affecting vWF:Ag

A variety of factors are known to affect measured vWF:Ag levels. Within individuals, levels can vary substantially over time, making classification into affected, carrier, or disease-free categories very difficult if based on a single sample. When blood is drawn from a cephalic vein, vWF:Ag levels are greater than when it is drawn from a jugular vein. Strenuous exercise, epinephrine, and pregnancy raise vWF levels (Moser et al., 1996). The effect of thyroid status has been debated; however, studies show no association between hypothyroidism and acquired vWD (Panciera and Johnson, 1996). It also has been shown that thyroid hormone supplementation to euthyroid Dobermans with vWD does not increase vWF concentration or activity (Heseltine, Panciera, and Troy, 2005). Blood type remains to be investigated but is known to have an effect in human vWD.

Therapy

The mode of therapy used to treat vWD depends on the presenting situation, although blood products generally are indicated in cases of ongoing or anticipated hemorrhage. If anemia is not present or mild, the use of fresh plasma, fresh-frozen plasma, or cryoprecipitate (CP) is recommended. CP is especially valuable since the clinician can give larger quantities of vWF without having to be concerned about volume overload. Administration of CP significantly increases vWF levels within 30 minutes of administration in Doberman pinschers with type I vWD, an effect that remains apparent for at least 4 hours (Ching et al., 1994). Similarly the BMBT was rapidly improved,

but by 4 hours it was at the same level as before treatment. In animals given fresh plasma the vWF level increased in a manner similar to that of patients given CP, but no improvement in BMBT occurred. The significance of this observation is unclear since clinical experience suggests that fresh plasma is effective in the treatment of vWD. Human recombinant vWF has been used experimentally in dogs with minimal effect and no change in observed bleeding times (Turecek et al., 1997).

Desmopressin acetate can also be useful in the treatment of vWD, especially in situations in which therapy is initiated to prevent or control hemorrhage in association with surgery. Desmopressin is used extensively in humans with vWD and appears to have a variety of effects that promote hemostasis, including the release of stored vWF from endothelial cells. In many dogs with vWD the increase in vWF is slight, although the BMBT decreases (Kraus et al., 1989). The onset of activity occurs in 30 minutes, and the duration of effect is approximately 2 hours. Since desmopressin releases stored vWF, repeating the injection has significantly less effect than the initial treatment. Desmopressin can be given to donor dogs to maximize vWF levels before phlebotomy. Although an intravenous product is available, its cost has led to the successful use of an intranasal product given subcutaneously at 1 to 4 mcg/kg.

HEMOPHILIA A

Hemophilia A is the most common inherited coagulation factor deficiency in dogs and is an X-linked recessive disease caused by factor VIII deficiency. Generally the female is the carrier, and only males express signs of the disease. However, a mating between a carrier female and an affected male would result in affected females. The disease has been diagnosed in more than 40 breeds and also in mixed-breed dogs. A higher prevalence is observed in German shepherd dogs. The clinical manifestations vary, depending on the degree of deficiency. As with most coagulopathies, body cavity hemorrhages (abdomen, thorax, and joints) and extensive bruising are the most common manifestations. In severely affected individuals death at birth can result from umbilical cord hemorrhage. In others the first clinical manifestations may be evident during teething. Since factor VIII is involved in the intrinsic coagulation pathway, prolongations of activated clotting time (ACT) and activated partial thromboplastin time (APTT) are seen. The diagnosis is verified by specific factor analysis. Factor VIII activity varies from 0% to 25% in affected animals, with disease being classified as mild (>5% factor activity), moderate (1% to 5% factor activity), and severe (<1% factor activity). Therapy for hemophilia A consists of administration of blood products. If red blood cells are needed because of anemia, whole blood can be given. Fresh-frozen plasma or CP is preferred if anemia is not present.

HEMOPHILIA B

Hemophilia B (Christmas disease) results from factor IX deficiency. The disease has an X-linked recessive mode of inheritance and has been identified in 19 breeds and mixed-breed dogs. Factor IX is a vitamin K-dependent protein produced in the liver. The clinical signs of hemophilia B mimic those encountered with hemophilia A.

The clinical manifestations vary in severity from mild to fatal hemorrhages. Unlike dogs with hemophilia A, dogs with factor IX deficiency invariably have less than 1% of normal factor activity detected. Both ACT and APTT are prolonged in dogs with this disease because factor IX is a part of the intrinsic coagulation pathway. The final diagnosis depends on specific factor analysis.

Therapy for factor IX deficiency consists of the administration of blood products. Fresh-frozen plasma or cryosupernatant is indicated when anemia is not marked. Factor IX is also found in serum, so it could also be given. Gene therapy with a liver-directed adenoviral vector holds promise.

Genetic Basis of Hemophilia A and B

The molecular basis of hemophilia A is not described. There have been five mutations described so far that result in hemophilia B. The genes coding for factors VIII and IX are highly mutable, allowing for a large number of mutations. Hemophilia frequently can result from spontaneous or new mutations.

Other Less Common Hereditary Coagulopathies

A variety of other coagulopathies have been identified in dogs (Fogh and Fogh, 1988). In some the only clinical manifestation is an alteration of routine hemostatic tests without an associated bleeding tendency. Definitive diagnosis requires testing by reference laboratories involved in research on coagulation disorders in animals. Hypofibrinogenemia (factor I deficiency) has been identified in Saint Bernard dogs associated with a prolongation of one-step prothrombin time (OSPT; extrinsic pathway of coagulation) and marked bleeding diathesis in severely affected animals. An autosomal-recessive factor II (prothrombin) deficiency has been identified in a family of boxer dogs with prolongation of OSPT. Bleeding was severe in some pups but was generally mild in adults. Factor VII deficiency has been identified as an autosomal-dominant disease in beagle dogs. Bleeding is rarely reported, although OSPT values are prolonged. In cocker spaniels factor X deficiency has been reported as an autosomal-dominant trait with a variable expression of the hemorrhagic tendency. Both APTT and OSPT are prolonged in this disease. Severely affected animals generally do not survive. Factor XI deficiency has been seen in Kerry blue terriers, Great Pyrenees, and English springer spaniels as an autosomal-recessive trait. The disease manifests as a prolongation of APTT and a variable bleeding tendency. Factor XII (Hageman factor) deficiency has been identified in miniature poodles but is much more commonly identified in cats. Deficiency of this factor causes a prolongation of APTT, but it is not associated with a bleeding tendency. Prekallikrein deficiency has been seen in a variety of breeds. It causes a prolongation of APTT, apparently without an associated tendency toward hemorrhage.

BLOOD PRODUCTS FOR COAGULOPATHY

Whole Blood

In cases in which anemia is a significant problem, fresh whole blood (less than 6 hours since collection) is the

product of choice. Factor VIII, vWF, and factor V are inactive when blood has been stored, but the vitamin K-dependent factors (factor II, VII, IX, and X) retain their activity. Canine donors should be negative for canine red cell antigens DEA 1.1, 1.2, and 7 (see Chapter 56). The volume of transfusion depends on the severity of the anemia, but a general guide is 12 to 24 ml/kg, which would be expected to raise the packed cell volume by 5% to 10%. The major drawback in treating a coagulopathy with blood is the volume overload that can occur, even though the quantity of coagulation factors given is small. Blood products containing red blood cells should be reserved for animals with significant anemia because transfusion can lead to sensitization to red cell antigens. Such sensitization could preclude safe administration of red cells at a later date, when they may be vitally needed. Local control of hemorrhage with bandages, pressure, and topical adhesives should always be used maximally to minimize need for transfusion therapy.

Fresh and Fresh-Frozen Plasma

Plasma harvested from whole blood within 6 hours of collection is termed *fresh plasma*. If this plasma is transfused within the 6-hour time frame, all vital coagulation protein activity is retained. Rapid separation from whole blood preserves the activity of factors V and VIII and vWF. Fresh plasma also contains albumin, complement proteins, antithrombin III, and immunoglobulins. Plasma frozen within 6 hours of the blood collection is termed *fresh-frozen plasma* and can be stored frozen (preferably at -70°C) and retain its coagulation activity for as long as 1 year. Usually 6 to 10 ml/kg is transfused, and this amount can be administered every 8 hours as needed. Volume overload is a consideration with plasma administration, especially when an animal is severely affected with vWD and needs multiple transfusions.

Stored or Frozen Plasma

Stored plasma results when plasma is separated from red blood cells more than 6 hours after collection. When frozen, this plasma is termed *frozen plasma*. It is deficient in factors V and VIII and vWF activity but does have the other coagulation factors present (including factor IX). It is generally not used in the treatment of coagulopathies.

Cryoprecipitate

When fresh-frozen plasma is slowly thawed (at 4°C), a precipitate is formed, called *CP*. Most of the factor VIII, fibrinogen, and vWF in the plasma is contained in the CP. It generally is only one tenth of the volume of the original plasma. The remainder of the plasma is called cryo-free plasma or cryosupernatant. Cryosupernatant still contains most of the other active coagulation factors and plasma proteins. CP and cryosupernatant can be frozen again and stored for as long as 1 year. The reported

concentration of vWF in CP varies from approximately four times that in the original plasma (Stokol and Parry, 1995) to twenty times the original (Ching et al., 1994). The larger multimers appear to preferentially precipitate (Ching et al., 1994). A dose of 1 unit of CP (CP produced from 150 ml of plasma) per 10 kilograms of body weight has been recommended. CP can be obtained from commercial animal blood banks.

Thrombocytopenia

JENNIFER A. NEEL, *Raleigh, North Carolina*

ADAM J. BIRKENHEUER, *Raleigh, North Carolina*

CAROL B. GRINDEM, *Raleigh, North Carolina*

Thrombocytopenia is the most common platelet disorder observed in dogs and cats. At our institution thrombocytopenia was found in approximately 5% of dogs presenting from 1996 to 2006 and 3.6% of cats presenting from 2004 to 2006. Previous studies at this university have shown that in dogs the etiology of thrombocytopenia is 5% primary immune mediated, 13% neoplasia, 23% infectious or inflammatory disease, and 59% miscellaneous or multifactorial causes (Grindem et al., 1991). In cats causes of thrombocytopenia included 2% primary immune mediated, 20% neoplasia, 29% infectious diseases, 7% cardiac diseases, 22% multiple etiologies, and 20% unknown causes (Jordan, Grindem, and Breitschwerdt, 1993).

Pseudothrombocytopenia occurs when platelets present in a specimen are not counted. This must be eliminated as the cause of a low platelet count. Platelet aggregation caused by activation during blood sampling is a major cause of falsely decreased counts and occurs commonly in cats; one study found low automated platelet counts in 71% of feline samples (Norman et al., 2001). Large platelets are also a cause of low platelet counts on some automated hematology analyzers when the size of the platelets overlaps with the size of red blood cells (RBCs). Ethylenediaminetetraacetic acid (EDTA)-induced platelet clumping has rarely been reported. Some breeds such as cavalier King Charles spaniels and greyhounds normally have lower platelet counts than most dogs or established platelet reference intervals.

MECHANISMS OF THROMBOCYTOPENIA

Thrombocytopenia occurs by one of four general mechanisms: decreased production, increased consumption/destruction, sequestration, and excessive loss. Often more than one mechanism occurs in any single disease or disorder. Decreased production is seen with suppression or destruction of megakaryocytes caused by immune-mediated disease, drugs, infectious agents, whole body irradiation, and myelophthitic disorders. Increased consumption or destruction is a common cause of thrombocytopenia in dogs and cats; etiologies include primary or secondary immune-mediated disease, drugs, disseminated intravascular coagulation (DIC) (vascular damage, septicemia, endotoxemia, massive tissue necrosis/damage, or release of procoagulant substances), disseminated neoplasia, and infectious diseases. Thrombocytopenia resulting from sequestration or abnormal distribution of platelets

can be caused by splenic congestion/splenomegaly, hepatomegaly, neoplasia, severe hypothermia in dogs, and experimentally induced endotoxemia. Marked thrombocytopenia is not typically noted, and the effect is often transient. Excessive loss can occur with massive blood loss and is observed in some cases of hemorrhage associated with rodenticide toxicity, but often platelet counts are normal to increased in these patients. This article focuses on causes and treatment of immune-mediated and infectious thrombocytopenia.

IMMUNE-MEDIATED THROMBOCYTOPENIA

Immune-mediated thrombocytopenia (IMTP) can be primary, secondary, vaccine induced, or posttransfusion. *Primary, or idiopathic, IMTP* is reported most commonly in dogs but has also been reported in cats. This is a disease of exclusion; other potential causes of secondary IMTP must be eliminated before a diagnosis of primary IMTP can be made. Acquired amegakaryocytic thrombocytopenia is a rare form of immune-mediated disease resulting from autoantibodies directed towards megakaryocytes. In a case series of four dogs, two had no evidence of concurrent disease (presumed idiopathic IMTP), and two had evidence of infectious disease (presumed secondary IMTP) (Lachowicz et al., 2004).

Secondary IMTP occurs when antibody targets non-self antigens adsorbed onto the surface of platelets or when immune complexes become bound to platelet surfaces. Underlying mechanisms include systemic autoimmune diseases (systemic lupus erythematosus), neoplasia, infectious agents, and drugs; but occasionally additional causes are identified. One report documents the presence of thrombocytopenia in 2.5% of dogs with idiopathic inflammatory bowel disease. Known causes of thrombocytopenia were eliminated, and the authors postulated that the thrombocytopenia was secondary to the primary disease (Ridgway, Jergens, and Niyo, 2001).

Thrombocytopenia associated with neoplasia is often multifactorial, with secondary immune-mediated destruction representing one potential component. Lymphoma in dogs has been associated most commonly with secondary IMTP, but it can occur with any neoplasm. In one study 10% of dogs with neoplasia had concurrent thrombocytopenia, and of this group 61% did not have identifiable factors known to cause secondary IMTP (Grindem et al., 1994). As with neoplasia, thrombocytopenia in

infectious diseases is often multifactorial and can include a secondary immune-mediated component. Antiplatelet antibodies have been detected in various infectious diseases, including *Ehrlichia canis* infections and Rocky Mountain spotted fever (RMSF). Drugs are rarely reported to cause a true primary IMTP; more typically it is secondary in nature (Kristensen, 2000). With this mechanism the drug acts as a hapten, allowing immune-mediated targeting of the platelets. A few drugs are capable of causing a secondary immune-mediated reaction without a history of prior exposure (heparin in horses), but most occur following extended use or prior exposure. Several documented cases involving trimethoprim sulfonamide/sulfamethoxazole have been reported in dogs, but it could potentially be caused any number of drugs. Vaccine-induced thrombocytopenia has been reported in dogs following immunization with modified live vaccines (canine distemper). Typically thrombocytopenia is mild and develops within 3 to 10 days after vaccination, but marked thrombocytopenia can occur. Posttransfusal thrombocytopenia has been reported occasionally in dogs.

INFECTIOUS ETIOLOGIES ASSOCIATED WITH THROMBOCYTOPENIA

See Table 60-1 for a list of infectious agents associated with thrombocytopenia in dogs and cats (Greene, 2006). Thrombocytopenia associated with infectious etiologies is often multifactorial, involving increased consumption, destruction, vasculitis, or sequestration; and in many cases the pathogenesis is incompletely understood. As mentioned previously, a number of agents are associated with secondary IMTP. Some are known to cause bone marrow suppression, including feline leukemia virus (FeLV) infection, feline immunodeficiency virus (FIV) infection, feline panleukopenia (parvovirus), canine parvovirus, and chronic monocytotropic ehrlichiosis (*Ehrlichia canis*, *Ehrlichia chaffeensis*). FeLV and FIV are of particular importance in feline thrombocytopenia. In one study 30% and 15% of thrombocytopenic cats tested positive for FeLV and FIV, respectively, indicating that these diseases are major causes of or contributing factors to the development of thrombocytopenia (Jordan, Grindem, and Breitschwerdt, 1993).

Table 60-1

Infectious Causes of Thrombocytopenia in Dogs and Cats

Disease	Species	Mechanism	Diagnostic Tests*	Therapy
Viral				
Canine distemper	C	U	Ag detection, PCR, serology	Supportive
Canine herpesvirus	C	V	Ag detection, serology, VI	Supportive
Canine parvovirus infection: canine parvovirus 2	C	P, U	Ag detection, EM feces, PCR, serology	Supportive
Infectious canine hepatitis: canine adenovirus 1	C	U, V	Serology, PCR, VI	Supportive
Feline immunodeficiency virus	F	P	Serology, PCR	Supportive
Feline infectious peritonitis: feline corona virus	F	U, V	Ag detection, histopathology, PCR, serology	Supportive
Feline leukemia virus	F	P	Ag detection, PCR, serology	Supportive
Feline panleukopenia/feline parvovirus	F	P, U	Ag detection, EM, fecal VI, PCR, serology	Supportive
Rickettsial, neorickettsial, anaplasma, mycoplasma				
Canine granulocytotropic anaplasmosis: <i>Anaplasma phagocytophilum</i>	C	D, U	Blood smear, PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Canine granulocytotropic ehrlichiosis: <i>Ehrlichia ewingii</i>	C	D, U	Blood smear, PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Canine monocytotropic ehrlichiosis: <i>Ehrlichia canis</i> , <i>Ehrlichia chaffeensis</i>	C	D, P, U	Blood smear, PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Feline granulocytotropic anaplasmosis: <i>A. phagocytophilum</i>	F	D?	PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Feline mononuclear ehrlichiosis: <i>E. canis</i> , <i>Neorickettsia risticii</i> (?)	F	D?	PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Hemotropic mycoplasmosis: <i>Mycoplasma haemofelis</i> , <i>Mycoplasma haemominutum</i> , <i>Mycoplasma haemocanis</i>	C, F	D, S	Ag detection, blood smear, PCR	Doxycycline (10mg/kg PO q24h for 21 days), Enrofloxacin (5 mg/kg PO q24h for 14 days)
Rocky mountain spotted fever: <i>Rickettsia rickettsii</i>	C	D, V	Ag detection (skin), PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)
Salmon poisoning disease: <i>Neorickettsia helminthoeca</i>	C	D, U	Cytology, fecal examination	Doxycycline (10mg/kg PO q24h for 21 days)
Thrombocytotropic ehrlichiosis: <i>Anaplasma platys</i>	C	D, U	Ag detection, blood smear, PCR, serology	Doxycycline (10mg/kg PO q24h for 21 days)

Table 60-1—Cont'd

Disease	Species	Mechanism	Diagnostic Tests*	Therapy
Bacterial				
Bacteremia/septicemia	C, F	D, U, V	Blood, urine, body fluid culture	Ampicillin sulbactam (30 mg/kg IV q8h) and Enrofloxacin (10 mg/kg IV q24h)
Bartonellosis: <i>Bartonella vinsonii</i>	C	D, V	Culture, PCR, serology	Optimal treatment is unknown. Azithromycin (5 mg/kg PO q24h for 5 days, then EOD for 45 days) has been recommended
Endotoxemia: most often <i>Escherichia</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Proteus</i> , <i>Pseudomonas</i>	C, F	S	Blood, urine, wound culture, often presumptive	Ampicillin sulbactam (30 mg/kg IV q8h) and Enrofloxacin (10 mg/kg IV q24h)
Leptospirosis	C	D, U, V	Ag detection, histopathology, PCR, serology, urine dark-field microscopy, urine or blood culture	Ampicillin (22 mg/kg IV q8h for 2 weeks) followed by Doxycycline (5 mg/kg PO q12h for 3 weeks). Some recommend Doxycycline for initial therapy
Plague: <i>Yersinia pestis</i>	F	S, U	Ag detection, culture, PCR, serology	Doxycycline (10 mg/kg PO q24h for 21 days), Enrofloxacin (5 mg/kg PO q24h for 14 days)
Salmonellosis	C, F	D, S, U, V	Culture, PCR	Enrofloxacin (5-10 mg/kg IV q24h) reserved for patients with septicemia
Tularemia: <i>Francisella tularensis</i>	C, F	D, U, V	Ag detection, culture, PCR, serology	Doxycycline (5 mg/kg PO q12h)
Protozoal				
Babesiosis: <i>Babesia canis</i> , <i>Babesia gibsoni</i>	C	U, S	Blood smear, PCR, serology	Imidocarb dipropionate (6.6 mg/kg IM twice, 2 weeks apart) for <i>B. canis</i> , Atovaquone (13.5 mg/kg PO q8h for 10 days) and azithromycin 10 mg/kg PO q24h for 10 days) for <i>B. gibsoni</i>
Cytauxzoonosis: <i>Cytauxzoon felis</i>	F	U, S	Blood smear, cytology, PCR†	Imidocarb dipropionate (2-3 mg/kg IM twice one week apart) or Atovaquone (15 mg/kg PO q8h for 10 days) and azithromycin 10 mg/kg PO q24h for 10 days
Leishmaniasis	C	U	Ag detection, cytology, PCR, serology, western blot analysis	Meglumine antimonite (100 mg/kg SQ q24h) and allopurinol (15 mg/kg PO q12h) for 3-4 months, allopurinol indefinitely
Toxoplasmosis: <i>Toxoplasma gondii</i>	C, F	U	Fecal (cats), serology, cytology	Clindamycin (12.5-25 mg/kg PO q12h)
Nemotodal				
Heartworm disease: <i>Dirofilaria immitis</i>	C	D, U, V	Ag detection, blood smear, Knott's test, serology	Melarsomine (2.5 mg/kg IM)
Fungal				
Disseminated candidiasis	C, F	U	Culture, cytology,	Itraconazole (5-10 mg/kg PO q12h)
Histoplasmosis: <i>Histoplasma capsulatum</i>	C, F	U	Ag detection, culture, cytology, serology	Itraconazole (5-10 mg/kg PO q12h)

Ag, antigen; C, canine; D, destruction; EM, electron microscopy; F, feline; PCR, polymerase chain reaction; S, sequestration; U, utilization; V, vasculitis; VI, virus isolation.

† Available at the North Carolina State University, Tick-Borne Disease Laboratory, Raleigh, NC.

‡ Uncertain.

DIC is commonly seen in gram-negative sepsis, infectious canine hepatitis (ICH), leptospirosis, salmonellosis, babesiosis (virulent strains), canine and feline parvovirus, cytauxzoonosis, and plague. Vascular damage occurs

in endotoxemia, septicemia, heartworm disease, feline infectious peritonitis (FIP), ICH, RMSF and bartonellosis. Platelet sequestration within the spleen, liver, or lungs is noted in endotoxemia; plague; salmonellosis;

babesiosis; cytauxzoonosis; and in hemolytic crisis secondary to babesiosis, hemotropic mycoplasmosis (formerly hemobartonellosis), or cytauxzoonosis. Etiologic agents vary with geographic location and may be limited by the vector, intermediate host, or environmental requirements of the organism.

The degree of thrombocytopenia can vary. Although thrombocytopenia is most severe in IMTP and overwhelming sepsis (counts of less than 50,000/ μ l and often fewer than 10,000/ μ l), it can be moderate to severe in canine monocytotropic ehrlichiosis. In one report on prevalence of *E. canis* infection in thrombocytopenic dogs in an endemic region, infection was found in 63.1% of dogs with a platelet count of less than 100,000/ μ l but in only 21% of dogs with platelet counts between 100,000 and 200,000/ μ l; nonthrombocytopenic dogs had an infection rate of 1.4% (Bulla et al., 2004). Severe, cyclic thrombocytopenia is also seen with thrombocytotropic ehrlichiosis, but dogs are not systemically sick; clinically ill dogs with this disease should be evaluated for concurrent tick-borne diseases such as monocytotropic ehrlichiosis.

Tests used to diagnose infectious diseases include serology, polymerase chain reaction (PCR), antigen detection in fluids or tissues, cytology, blood smear evaluation, culture, virus isolation, electron microscopy, and histopathology (see Table 60-1; Greene, 2006).

CLINICAL EVALUATION OF THROMBOCYTOPENIA

Because thrombocytopenia typically is secondary to another disease or condition, signalment, history, and physical examination findings are extremely important. Primary IMTP is more commonly reported in middle-aged female dogs, especially cocker spaniels, German shepherds, poodles, and Old English sheepdogs, but can occur in any breed at any age. Most animals present for signs relating to the underlying disease, or the thrombocytopenia is found serendipitously on routine blood work. Risk of bleeding increases as platelet counts decrease below 20,000/ μ l, although spontaneous bleeding typically does not occur, even with marked thrombocytopenia. We have seen primary IMTP in dogs with platelet counts of fewer than 5000/ μ l that have no bleeding tendencies or clinical signs.

When present, signs directly related to thrombocytopenia can include petechiae, ecchymoses, prolonged bleeding after trauma, venipuncture, whelping or surgical procedures, prolonged estrus, bruising, melena, hematemesis, intraocular hemorrhage or blindness, hematuria, oral bleeding, neurologic signs associated with cerebral bleeding, and epistaxis. Petechiae and ecchymoses are easiest to identify on mucous membranes or thin-skinned regions such as the abdomen. Other signs related to the underlying cause of thrombocytopenia may include fever, weight loss, enlarged lymph nodes, splenomegaly, hepatomegaly, abdominal masses, stiffness, joint pain, neurologic signs, or edema.

A careful and thorough history can provide valuable clues to the etiology of thrombocytopenia. Vaccination history; FeLV and FIV status; exposure to drugs or tox-

ins; travel history; exposure to infectious agents, ticks, or other animals; history of previous illnesses; tick/flea/heartworm preventive use; indoor/outdoor status; and clinical signs or changes noted by the owner should all be ascertained.

DIAGNOSTIC APPROACH TO INFECTIOUS OR IMMUNE-MEDIATED THROMBOCYTOPENIA

The first step is to confirm the presence of thrombocytopenia by performing a complete blood count with an automated platelet count and examining a peripheral blood smear. Extremely high or low platelet counts may not be assessed accurately by automated instruments if they are outside instrument linearity, and platelet clumps or large platelets can result in spuriously low counts. For these reasons abnormal automated platelet counts must always be confirmed by examination of a blood smear. Platelet clumping is best appreciated along the feathered edge of the smear and, if present, indicates that a new sample must be collected. If repeated samples yield clumped platelets, blood can be collected into a syringe rinsed with EDTA. Alternatively a needle can be inserted into a peripheral vein, and blood collected directly from the hub into the capillary tube of a Unopette manual white blood cell and platelet count system (Becton Dickinson) for a manual platelet count. When clumps are found, platelets typically are present in sufficient numbers to prevent spontaneous hemorrhage. If clumps are not present, the platelet count can be estimated by multiplying the mean platelet count in ten 100 \times fields within the monolayer of the blood film by 15,000 to give the total platelet count per microliters. A patient with a normal or increased platelet count with signs of a primary hemostatic defect (petechia, ecchymosis) should be evaluated for platelet function defects or vascular disorders.

Platelet size and morphology should also be evaluated in the thrombocytopenic patient. Large platelets are an indication of increased platelet production and support a regenerative response by the bone marrow. Normal-size platelets may be seen in acute disorders in which the bone marrow has not had time to respond, or they can indicate a hyporesponsive or unresponsive marrow. Small platelets or platelet fragments can be associated with early or nonregenerative IMTP. *Anaplasma platys* may be identified as stippled blue morulae within platelets during clinical episodes.

Evaluation of the erythrogram, leukogram, and a peripheral blood smear can help distinguish decreased platelet production from increased use or destruction. Decreased production or suppression of only the megakaryocytic line is rare; most etiologies are associated with decreased production or suppression of the myeloid and erythroid series as well. Typically a peripheral neutropenia without a left shift is seen. A nonregenerative anemia may be present in long-standing conditions but is not expected in acute conditions or conditions of short duration because of the long life span of RBCs (110 days in dogs, 68 days in cats). Conditions or diseases causing increased platelet destruction or consumption are often associated with an inflammatory leukogram characterized by a neutrophilia

or neutropenia with a left shift. Toxic change may also be seen in a variety of inflammatory conditions; when moderate to marked, it is most indicative of a bacterial infection. A mild, nonregenerative anemia (anemia of inflammatory disease) often accompanies inflammatory conditions. Although classically associated with chronic conditions, this anemia can develop within a week of the onset of significant inflammation. Evidence of hemolytic disease may be seen with some etiologic agents such as *Babesia*, *Cytauxzoon*, and *Mycoplasma*; these agents may also be identified in RBCs on a peripheral blood smear. Morulae may be found within neutrophils in acute canine granulocytotropic ehrlichiosis and anaplasmosis or in monocytes in monocytotropic ehrlichiosis. IMTP can also accompany primary or secondary immune-mediated hemolytic anemia, which is classically characterized by a regenerative anemia with spherocytosis and an inflammatory leukogram. Vasculitis and DIC often result in circulating schistocytes.

Examination of the bone marrow may be indicated if the cause of the thrombocytopenia is not apparent from the routine clinical evaluation. Other indications for bone marrow examination include suspicion of leukemia, multiple myeloma, lymphoma or other myeloproliferative disorder, or the presence of multiple cytopenias of unknown etiology. Collection of a bone marrow aspirate for cytology and a bone marrow core biopsy for histopathology is ideal; these provide the greatest amount of information when interpreted together. Even when thrombocytopenia is severe, it is not a contraindication for performing a bone marrow biopsy. Patients rarely have significant hemorrhage from the procedure; however, it is wise to choose a site without significant muscle mass such as the proximal humerus where hemorrhage can be more easily controlled. Transfusion may be necessary before performing the biopsy if the patient is bleeding actively. Increased numbers and immaturity of megakaryocytes indicate a regenerative response; decreased numbers indicate an unresponsive or preregenerative marrow (a regenerative response should occur within 3 to 5 days of acute thrombocytopenia).

A coagulation profile consisting of prothrombin time (PT), activated partial thromboplastin time (APTT), and fibrin degradation products (FDPs) should ideally be performed in all animals with thrombocytopenia. D-dimer levels may also be useful in dogs. Fulminant DIC is classically characterized by a prolonged PT and APTT with significantly increased FDPs and D-dimer levels, but peracute or chronic DIC should not be ruled out if coagulation parameters are within reference intervals and clinical suspicion of DIC is high. DIC is a common secondary condition in a variety of infectious, inflammatory, and neoplastic diseases and is triggered by vascular damage, massive tissue damage, or release of activating substances (see Chapter 61 for more information). Hemorrhage caused by rodenticide toxicity is characterized by markedly prolonged PT and APTT with normal FDPs or D-dimer levels. The proteins inhibited by vitamin K antagonism or absence (PIVKA) test can confirm rodenticide poisoning.

Selection of additional diagnostic tests is based on information provided by the patient's history, signalment, physical examination findings, and initial blood work. EDTA anticoagulated blood and a serum sample

should be collected and saved for serology, PCR, and culture and antiplatelet antibody assays; it is important to collect these specimens before initiating therapy. Culture of blood or other fluids/tissues should be performed on any animal with suspected septicemia. Survey radiographs or ultrasonography may be indicated. Enlarged lymph nodes or organs, masses, and effusions should be examined via cytology or histopathology. Joint fluid should be collected and examined cytologically in animals with joint pain or swelling, and cerebrospinal fluid (CSF) collection and cytologic evaluation may be indicated in animals with neurologic disease. Titers for infectious diseases, PCR, and culture can also be performed on joint fluid or CSF. For animals with suspected systemic immune-mediated disease, antinuclear antibody testing, antithrombotic antibody testing (Coombs' test), and potentially histopathologic and immunohistochemical examination of dermal lesions should be performed.

Tests to confirm IMTP are available, but it is important to remember that no test can distinguish primary from secondary disease; thus all causes of secondary immune-mediated disease must be ruled out before a diagnosis of primary IMTP can be made. Tests can detect platelet-bindable autoantibodies in patient serum or plasma (indirect assays) or antibody present on the surface of platelets or megakaryocytes (direct assays). Direct assays are preferred because they are more specific; indirect assays fail to differentiate autoimmune antibodies from alloantibodies, circulating immune complexes, or nonspecific immunoglobulin G aggregates formed in stored serum. Shipping and handling potentially can be problematic for direct antiplatelet antibody assays; thus it is advisable to contact the reference laboratory regarding sample handling before collection and shipping. The direct megakaryocytic immunofluorescence assay (D-MIFA) circumvents sample handling issues by using unstained, air-dried bone marrow smears. When using this assay, it is important to remember that poorly cellular specimens or specimens with inadequate numbers of megakaryocytes preclude adequate evaluation. In addition, autoantibodies targeting platelets may not target megakaryocytes; thus a negative result cannot be used to rule out immune-mediated disease. Low sensitivity has been reported with this test (Kristensen, 2000).

THERAPY

The goals of treatment are to stop hemorrhage, halt ongoing platelet destruction, and treat any underlying disorders. Treatment usually consists of a combination of both specific and supportive measures. Supportive measures include the use of blood products (whole blood or packed red blood cells) or purified polymerized bovine hemoglobin solutions to maintain oxygen delivery to tissues and crystalloid fluids to maintain hydration in patients that are anorexic and not drinking. Venous access may not be necessary in patients that are stable. When intravenous access is needed, catheterization of the jugular vein is contraindicated in patients with severe thrombocytopenia because of the difficulty in controlling hemorrhage at this site. The use of fresh-frozen plasma is limited to patients with concurrent coagulopathies associated with decreased clotting factors such as rodenticide intoxication

or DIC. Platelet transfusions have limited use because of difficulty in transfusing a large enough number of platelets to exert a clinical benefit combined with the short circulating half-life of transfused platelets in patients with destructive platelet disorders. Platelet transfusions may provide transient improvement in hemostasis but typically do not increase detectable platelet counts. They can be performed using platelet concentrates, platelet-rich plasma, or whole blood and should be reserved for patients with life-threatening hemorrhage. Since the gastrointestinal tract is the most common site of significant bleeding secondary to thrombocytopenia, gastroprotectants (sucralfate, H_2 blockers, proton-pump inhibitors) are frequently used. However, since true ulceration is rarely present in dogs with IMTP, the use of these drugs for gastrointestinal bleeding secondary to thrombocytopenia is questionable.

If an underlying infectious cause of thrombocytopenia is identified or highly suspected, specific therapy should be instituted. Treatments for selected infectious causes of thrombocytopenia are listed in Table 60-1. In patients that are stable and not experiencing life-threatening hemorrhage, antimicrobial therapy alone may be sufficient to resolve the thrombocytopenia. However, specific therapy against infectious agents may not be sufficient to halt the immune-mediated destructive process, and concurrent immunosuppressive therapy may be indicated. When immunosuppressive and antimicrobial therapy are started concurrently, worsening of infection from the immunosuppressive therapy is rare, except with systemic fungal infections or cases in which immunosuppression has been ongoing for weeks to months before antimicrobial therapy. When instituted simultaneously in cases with IMTP secondary to infectious diseases, immunosuppressive therapy frequently can be weaned more quickly (i.e., 25% dose reductions every 2 weeks) than in dogs with primary IMTP.

When no underlying cause of IMTP can be identified, immunosuppressive therapy is the treatment of choice. Corticosteroids remain the backbone of therapy for the treatment of primary IMTP. Prednisone is usually administered at a dose of 1 to 2 mg/kg every 12 hours orally for a minimum of 3 to 4 weeks or at least until the platelet count is greater than 200,000/ μ l. Vincristine (0.02 mg/kg intravenously once) has been used in patients with IMTP and was associated with shorter hospitalization times (Rosanski EA et al., 2002). If treatment with corticosteroids and vincristine do not result in increased platelet counts within 7 to 10 days, one or more adjunctive immunosuppressive drugs should be used (Table 60-2; see Chapter 55).

Long-term immunosuppressive therapy (≥ 6 months) is necessary for most cases of primary IMTP, and client expectations should be set accordingly. Some patients may require lifelong therapy to maintain normal platelet counts. The main cause for the relapse of thrombocytopenia in our experience is rapid corticosteroid taper (i.e., dose reductions at intervals equal to or less than 2 weeks) and/or failure to document the platelet count before each dose reduction. Tapering of the corticosteroid dose by approximately 25% of the current dosage every 3 to 4 weeks should only be attempted after

Table 60-2

Adjunctive Immune Suppressive Therapies

Drug	Dose	Side Effects/Monitoring
Azathioprine	2 mg/kg PO q24h for 2 weeks, then 2 mg/kg PO every other day	Bone marrow suppression, hepatotoxicity, pancreatitis, complete blood counts, serum biochemical profiles
Cyclosporine	5-10 mg/kg PO q12h	Vomiting, diarrhea, therapeutic drug monitoring
Human γ -globulin	0.5-1 g/kg IV over 6-12 hours once	Anaphylaxis, thromboembolism
Mycophenolate mofetil	10-20 mg/kg PO q12h	Vomiting, diarrhea, pyoderma

IV, Intravenously; PO, orally.

the platelet count has returned to, and remained within, the reference interval. Steroids can usually be discontinued completely when the dose administered is similar to the physiologic amount of cortisol produced in a normal patient (0.2 mg/kg/day of prednisone). If thrombocytopenia recurs during the tapering of the corticosteroids, the dose should be increased to the *original* dose, and adjunctive immunosuppressive drugs should be added if not already in use (see Table 60-2). Corticosteroids should then be tapered as before, down to the last dose at which a normal platelet count was detected. This dose is often maintained indefinitely or for a minimum of several months before tapering of corticosteroids is attempted again.

Splenectomy has been recommended as an adjunctive treatment for thrombocytopenia. This should typically be considered as a last resort; and thorough screening for infectious diseases, particularly babesiosis, should be performed before the procedure. Splenectomy can exacerbate hemoparasite infections and is associated with resistance to antiprotozoal treatments.

The prognosis for IMTP is guarded to good. In some university studies mortality rates have been 25% to 30%, but these often represent the most severe cases. Although formal studies of prognostic indicators for survival are minimal, most clinicians agree that clinically significant bleeding with anemia and intracranial hemorrhage are the worst prognostic indicators. The severity of the thrombocytopenia does not appear to be a significant prognostic indicator.

CHAPTER 61

Disseminated Intravascular Coagulation: Diagnosis and Management

ELKE RUDLOFF, *Glendale, Wisconsin*
REBECCA KIRBY, *Glendale, Wisconsin*

Disseminated intravascular coagulation (DIC) is a syndrome characterized by systemic microthrombosis, which can progress to life-threatening hemorrhage. DIC is reported in dogs but is less commonly recognized in cats. The DIC syndrome occurs secondary to an underlying acute or chronic condition associated with one or more of the following: systemic inflammation, tissue necrosis, capillary stasis, loss of vascular integrity, red cell hemolysis, and particulate matter in the blood.

PATHOGENESIS

The pathogenesis of DIC is characterized by: (1) increased thrombin production, (2) suppression of physiologic anticoagulant pathways, (3) impaired fibrinolysis, and (4) activation of inflammatory pathways (Fig. 61-1). Tissue factor (TF) is expressed on monocytes and endothelial cells within the circulation during inflammation and on malignant cells in cancer patients. The tissue factor: factor VIIa complex (extrinsic pathway), the main stimulus for thrombin formation in DIC, activates factor IX (intrinsic pathway) and factor X (common pathway) (Fig. 61-2). In human cancer patients DIC can also involve the

expression of a specific cancer procoagulant, a cysteine protease that has factor X-activating properties.

Impaired function of the normal physiologic anticoagulant pathways (see Fig. 61-2; Fig. 61-3) during DIC allows thrombin generation and the resultant fibrin formation to become exaggerated. Antithrombin (AT), a natural anticoagulant, binds to thrombin; inactivating thrombin; and factors IXa, Xa, XIa, and TF:FVIIa. During DIC AT levels are reduced as a result of increased AT consumption by AT-thrombin complex formation, AT degradation by neutrophil elastase, impaired hepatic synthesis of AT, and loss of AT because of increased capillary permeability. Depression of endogenous anticoagulant protein C:protein S activity results from enhanced consumption, impaired hepatic synthesis, and capillary leakage. In addition, proinflammatory cytokines (tumor necrosis factor [TNF]- α and interleukin [IL]-1 β) can cause down-regulation of protein C-thrombomodulin expression on endothelial cell surfaces.

During DIC fibrin deposition typically surpasses fibrinolysis. The release of plasminogen activators from endothelial cells rapidly initially increases fibrinolytic activity during sepsis. However, this is usually followed

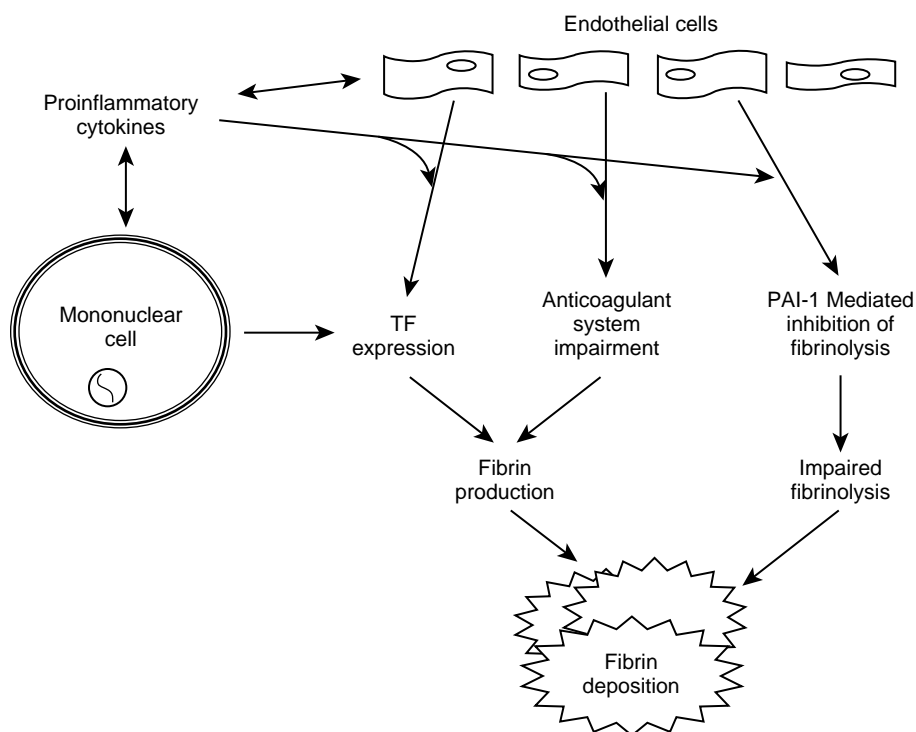

Fig. 61-1 Alterations in coagulation and anticoagulation during systemic inflammation and DIC. Fibrin deposition exceeds fibrinolysis when tissue factor (TF) expression is enhanced, the anticoagulation system is impaired, and levels of plasminogen activator inhibitor, type-1 (PAI-1) are increased.

by a prompt suppression of fibrinolytic activity caused by endothelial release of plasminogen activators and increased plasma levels of plasminogen activator inhibitor, type-1. In contrast, people with acute promyelocytic leukemia may exhibit a severe hyperfibrinolytic state associated with systemic coagulation activation.

The “cross talk” between the coagulation system and the inflammatory reaction is an important factor contributing to DIC pathogenesis (see Fig. 61-1). Activated coagulation proteins stimulate the endothelial cells to release inflammatory cytokines. Recruited white blood cells release $\text{TNF-}\alpha$ (activating factor VII), IL-1, and IL-6 (activating factors VII and XII). Platelet-activating factor,

a strong promoter of platelet aggregation, is also released from inflammatory cells. Additional activation of the inflammatory cascade is promoted by thrombin and other serine proteases interacting with protease-activated receptors on cell surfaces. The typical antiinflammatory effect of activated protein C is lost with depression of the protein C system during DIC, thereby enhancing the proinflammatory state of DIC.

It is important to recognize that the hypercoagulable condition occurs early in the course of DIC and bleeding associated with prolongation of coagulation times occurs later in the course of DIC. As a consequence of coagulation activation, platelets, coagulation factors,

Fig. 61-2 Coagulation during inflammation promoting thrombin and fibrin production. Tissue factor (TF) is the prime initiator of coagulation. Amplification of the coagulation scheme during DIC occurs by activation of factor IX (cross talk) and continued activation of factors VIII and IX and platelet surfaces by thrombin (feedback). Plasminogen activator inhibitor-type 1 (PAI-1) prevents plasmin activation and fibrinolysis. During inflammation there is inhibition of fibrinolysis when PAI-1 is up-regulated and promotion of fibrin deposition. Ca^{++} , Calcium; PL, phospholipase.

Fig. 61-3 This scheme depicts anticoagulation, which should normally balance coagulation. Tissue factor pathway inhibitor (TFPI) is a protease inhibitor of tissue factor complex. Bound to thrombin, anti-thrombin (AT) inactivates thrombin and factors IXa, Xa, XIa, and TF:FVIIa. Protein-C: Protein-S (PCPS) system irreversibly inactivates factors Va and VIIIa. Activation of plasminogen produces plasmin, which lysis fibrin and fibrinogen into fibrin degradation products and fibrin monomers. During inflammation there is consumption and inhibition of the anticoagulants and promotion of fibrin deposition.

and anticoagulants are consumed, degraded, and/or inhibited. A transition from accelerated coagulation to consumption of coagulants and anticoagulants corresponds with the clinical consequences of microthrombosis and vascular occlusion followed by uncontrolled hemorrhage. Therefore variations and combinations of the coagulation-anticoagulation-fibrinolytic-inflammatory derangements exist, depending on the underlying cause and coexisting disease processes. Diagnosis of an active DIC process is made through clinical findings and laboratory testing.

CLINICAL FINDINGS

DIC should be an anticipated complication in any animal experiencing one or more of the following: hypotensive crisis, impaired blood flow to a major organ, systemic inflammatory response syndrome, and/or release of vasoactive agents into the vasculature (Box 61-1). The severity of clinical signs associated with DIC can range from no signs to life-threatening complications of vascular microthrombosis reflected by organ dysfunction and/or evidence of systemic bleeding. Clinical signs can vary as DIC progresses.

The earliest (peracute) phase of DIC typically is characterized by subtle abnormal laboratory findings (Table 61-1) without obvious clinical signs. Clinical signs more compatible with the acute (days to weeks) phase of DIC include evidence of organ dysfunction from microthrombosis and/or hemorrhage with laboratory findings suggestive of alterations in hemostasis. Animals experiencing consumption of endogenous coagulation proteins during this phase can demonstrate bleeding from venipuncture sites, bleeding along the gum line, petechiae, ecchymosis, purpura, hematomas, and/or hemarthrosis.

The chronic phase (weeks to months) of DIC can develop from low-grade or intermittent procoagulant release (see Box 61-1). In the compensated state of chronic DIC, time exists for replenishment of coagulation factors, anticoagulation proteins, and platelets. There may

be abnormal laboratory findings without obvious clinical signs (see Table 61-1). Stress, concurrent disease, and disease progression can cause decompensation, abnormal laboratory findings, and clinical signs associated with microthrombosis and/or hemorrhage.

Box 61-1

Disease States Associated With Disseminated Intravascular Coagulation

Peracute

- Sepsis (bacterial, viral, fungal, protozoal)
- Severe gastroenteritis
- Vascular disorders
- Immune-mediated disorders
- Severe toxic or immunologic reactions (e.g., viper envenomation)
- Transfusion reaction
- Severe hepatic failure

Acute

- Sepsis (bacterial, viral, fungal, protozoal)
- Trauma/crush injuries
- Pancreatitis
- Burns/heatstroke
- Severe gastroenteritis
- Vascular disorders
- Immune-mediated disorders
- Severe toxic or immunologic reactions (e.g., viper envenomation)
- Transfusion reaction
- Severe hepatic failure
- Neoplasia

Chronic

- Neoplasia
- Protein-losing nephropathy
- Protein-losing enteropathy
- Heartworm disease
- Chronic hepatic disease
- Vascular disorders
- Hyperadrenocorticism

Table 61-1

Laboratory Values Supporting a Diagnosis of DIC

Test	Peracute	Acute	Chronic
Prothrombin time	N or ↓	N or ↑	N
Partial thromboplastin time	N or ↓	N or ↑	N
Activated clotting time	N or ↓	N or ↑	N
Platelets	N or ↓	↓	N
Fibrinogen	N or ↓	N or ↓ or ↑	N or ↓ or ↑
Fibrin degradation products	N or ↑	↑	N or ↑
D-dimer	N or ↑	↑	↑
Antithrombin	N or ↓	↓	N or ↓

N, Normal.

LABORATORY FINDINGS

No single laboratory test is sufficiently sensitive or specific to confirm a diagnosis of DIC. A diagnosis of DIC can be made when a clinical condition known to be associated with DIC and a combination of the following laboratory findings is present (also see Table 61-1):

1. Prolongation of coagulation times
2. Reduction in platelet numbers
3. Elevation of D-dimer or soluble fibrin
4. Decrease in AT activity
5. Clinical or postmortem evidence of thrombosis.

Stokol and colleagues (2001) report that a negative D-dimer test in dogs excludes DIC as a diagnosis with a confidence interval of 95%.

A scoring algorithm is used in humans with an underlying condition known to be associated with DIC. The scoring system incorporates a decreased platelet count, prolongation of prothrombin time, decreased fibrinogen, and increasing plasma levels of a fibrin-related marker (D-dimer, soluble fibrin or fibrin degradation products [FDPs]) as predictive of DIC. The use of fibrinogen to predict DIC can be questioned because fibrinogen levels are influenced by many factors other than DIC. An alternate scoring system in humans evaluates a dynamic coagulopathy score in which changes in AT, prothrombin time, and D-dimers are used. A similar scoring system is under investigation in veterinary medicine to assist in the diagnosis of DIC and the categorization of DIC to predict mortality.

THERAPY

Once a disease process associated with DIC has been identified, early recognition and aggressive therapy can improve outcome. Therapy is focused on promoting capillary blood flow, eliminating the underlying cause, supporting target organs, replacement therapy, and anticoagulants.

Promoting Capillary Blood Flow

Restoring capillary blood flow and tissue oxygenation requires rapid intravascular volume resuscitation

of perfusion deficits. Administering a combination of crystalloids with synthetic colloids (see Chapter 11 for more information on colloid therapy) increases capillary fluid volume and improves microvascular flow. Dextran-70 and hetastarch may improve flow dynamics and reduce platelet aggregation during hypercoagulable states. Red blood cell transfusions are used when hemoglobin levels have dropped precipitously (<8 to 10 g/dl). Oxyglobin (Biopure), a hemoglobin-based oxygen carrier approved for use in dogs, provides colloid osmotic pressure and oxygen-carrying molecules for the transport of oxygen to tissue beds experiencing maldistribution of blood flow. The vasoconstricting property of Oxyglobin can aid in reversing hypotension that is refractory to standard crystalloid and synthetic colloid infusion. Maintaining capillary flow depends on meeting ongoing fluid needs through continuous crystalloid and colloid infusions.

Eliminating Underlying Cause

Identification and treatment of the underlying disease process is crucial to the elimination of DIC. When a septic process is suspected, tissue and fluid samples are collected for histopathology, cytology, culture and sensitivity, and serology testing. Antimicrobial therapy for bacterial, protozoal, or fungal etiologies is initiated as early in the disease course as deemed appropriate. Removal and/or drainage of infected, torsed, ischemic, or necrotic tissue may be necessary. Antivenom and specific antidotes are used when indicated. Immune-mediated diseases require immunosuppressive medications. Neoplastic conditions may require surgical or medical treatment. Animals with medical conditions such as pancreatitis, severe gastroenteritis, or liver failure require aggressive cardiovascular support throughout hospitalization to minimize the effects of DIC during medical management.

Supporting Target Organs

Organs with high blood flow or high oxygen requirements are more susceptible to microthrombosis, hemorrhage, or tissue hypoxia secondary to DIC. Oxygen therapy, either with or without ventilatory support, may be necessary when hypoxemia or hypoventilation results from pulmonary pathology. Renal insufficiency and oliguria may require administration of diuretics and low-dose dopamine infusion (1 to 3 mcg/kg/minute) to promote afferent arteriolar dilation and renal blood flow. Early enteral nutrition supports gastrointestinal mucosal integrity.

Replacement Therapy**Blood Products**

Correction of coagulation times (prothrombin and partial thromboplastin time) to normal is usually not possible when DIC is ongoing. The volume of blood products required varies among patients. Factors used to determine type and dose of transfusion include degree of factor deficiency, degree of anemia, and the patient's volume status.

Plasma transfusion can be administered to rebalance coagulant and anticoagulant proteins. Fresh whole blood

and fresh frozen plasma contain all coagulation factors and AT. Stored whole blood and frozen plasma lack factors V and VIII. Fresh whole blood, platelet-rich plasma, or platelet concentrate are needed to provide platelets if bleeding attributed to thrombocytopenia is causing organ malfunction (e.g., ocular hemorrhage, myocardial arrhythmias, increased intracranial pressure). When significant anemia is present, fresh or stored whole blood, packed red blood cells, or Oxyglobin is given to improve oxygen-carrying capacity (see Chapter 58).

Antithrombin

AT activity accelerated by heparin inactivates thrombin and factors IXa, Xa, XIa, and TF:VIIa. In addition, AT binds to heparin sulfate proteoglycan receptors on the endothelial surface, stimulating the production of the antiinflammatory and antiplatelet cytokine prostacyclin. AT binds directly to cellular receptors on neutrophils and monocytes, limiting proinflammatory signaling. In phase III clinical trials high-dose recombinant AT has not been associated with a significant improvement in mortality in humans unless it is used without heparin (Warren et al., 2001). Recombinant human AT concentrate has not been investigated clinically in animal patients with DIC. Allogeneic AT can be infused in the form of plasma products when AT replacement is desired. The use of heparin in conjunction with AT supplementation is controversial (see section on Heparin later in the chapter).

Activated Protein C

Recent large-scale phase III clinical trials in humans with severe sepsis have shown a reduction in organ damage and mortality when recombinant human activated protein C (APC) was administered early in the course of disease. Additional benefits included a decrease in inflammatory cytokines and improved clotting times. The use of recombinant human APC or allogenic plasma transfusion for APC replacement has not yet been investigated clinically in veterinary patients.

Anticoagulant Therapy

Aspirin

Aspirin is a nonreversible thromboxane-2 inhibitor that reduces platelet aggregation and adhesion. Aspirin is used for reducing thrombotic events in people with coronary artery disease. Low-dose aspirin administration (0.05 mg/kg q24h orally) has been associated with reduced mortality in dogs with immune-mediated hemolytic anemia (a disease associated with DIC) receiving azathioprine and prednisone. Further studies still need to be performed to determine its use for other forms of DIC.

Heparin

Heparin is a glycosaminoglycan that exerts an antithrombotic effect by binding to and potentiating the inhibitory

actions of AT on thrombin and factors IXa, Xa, XIa, and TF:VIIa. Heparin administration has been established as beneficial for the prevention of venous thrombosis in people. Heparin therapy has been a long-standing mainstay of DIC therapy, but its use has become controversial. A beneficial effect of heparin on DIC has not been demonstrated in controlled clinical trials in humans and can be detrimental when overt bleeding is occurring. Heparin is ineffective in patients with reduced plasma levels of AT. In critically ill dogs heparin administration has been shown to further decrease AT levels (Rozanski et al., 2001). Binding of heparin to AT can reduce AT anti-inflammatory effects (see section on Antithrombin earlier in the chapter).

Heparin cannot eliminate existing thrombi but can help prevent the formation of new thrombi or expansion of established thrombi. At this time there is insufficient information to advocate the use of heparin in any phase of DIC. Heparin therapy may be most useful for patients with chronic DIC conditions in which there is predominantly a prothrombotic stage of DIC and no significant inflammatory stimulus.

Tissue Factor Pathway Inhibitors

A number of agents targeting the TF pathway are currently under study, including TF pathway inhibitor (TFPI), recombinant nematode anticoagulant protein C2 (NAPc2), recombinant hyrudin, and inactivated factor VIIa. Phase III clinical trials in humans are lacking, and use in veterinary medicine has not at this time been investigated.

Platelet Dysfunction

MARJORY B. BROOKS, *Ithaca, New York*
JAMES L. CATALFAMO, *Ithaca, New York*

Platelets are small, anucleated cell fragments, yet their active participation is crucial for initiating and regulating hemostasis. This chapter describes the clinical management of bleeding diatheses caused by thrombopathia, or platelet dysfunction.

NORMAL PLATELET FUNCTION

Platelets circulate in the vascular compartment as discrete, nonadhesive, smooth disks. When a blood vessel is injured, platelets are rapidly transformed into adhesive spiny spheres that attach to the damaged subendothelial surface and to each other. The adherent platelets release numerous substances from platelet storage organelles. These substances accumulate locally and recruit additional platelets to the injury site. As local platelet numbers increase, platelet aggregates accumulate and bridge the zone of vascular damage to form a hemostatic plug. The plug is stabilized by the generation of a thrombin-mediated platelet fibrin meshwork that traps platelets and red blood cells. The growing clot is later consolidated by the action of platelet contractile proteins that retract the clot (Colman et al, 1994).

The ability of platelets to respond to injury-induced stimuli is central to their role in maintaining vascular integrity (Fig. 62-1). These stimuli initiate platelet activation by mediating a change in concentration of intracellular second messengers such as ionized calcium, inositol triphosphate, diacylglycerol, and arachidonic acid metabolites. Prostacyclin (PGI_2) and prostaglandin E_2 (PGE_2) and D_2 (PGD_2) are endoperoxides synthesized by endothelial cells and released into the vascular space. PGI_2 inhibits platelet reactivity by elevating intraplatelet cyclic adenosine monophosphate (cAMP) and decreasing free ionized calcium and inositol phosphate formation. Prostaglandin E_2 and PGD_2 modulate expression of endothelial cell adhesion molecules. Endothelium-derived nitric oxide can also reduce platelet responsiveness by raising the level of intracellular cyclic guanosine monophosphate (cGMP).

The rapid transition from nonadhesive disk to adhesive sphere requires that platelets recognize cell adhesion molecules in the plasma and subendothelial matrix. Adhesion (platelet-subendothelial matrix interactions) and aggregation (platelet-platelet association) depend on integrin and other platelet glycoprotein (GP) receptors. Integrin receptors (GPs) are composed of α - and β -subunits. The GPIIb/IIIa ($\alpha_{\text{IIb}}\beta_3$) complex is the most abundant platelet integrin and functions as the activation-dependent receptor for fibrinogen, fibronectin, and von Willebrand's factor (vWF). The binding

of fibrinogen to this receptor is essential for normal platelet aggregation. Platelet adhesion and aggregation at high shear rates depends on vWF binding to GPIb-IX-V. Platelet adhesion to collagen is supported by its binding to the integrin receptor GPIa/IIa ($\alpha_2\beta_1$). This receptor and GPVI are also involved in signaling collagen-induced platelet activation.

CLINICAL SIGNS OF PLATELET DYSFUNCTION

The characteristic signs of platelet dysfunction include cutaneous ecchymoses, bleeding from mucosal surfaces (gingival hemorrhage, epistaxis, melena, hematuria), and prolonged or excessive bleeding at the sites of surgery or trauma. Pinpoint hemorrhage or petechiae are more commonly seen in thrombocytopenic patients, but there are no pathognomonic signs to differentiate platelet dysfunction from other primary hemostatic disorders. The systemic diseases that cause acquired platelet dysfunction often cause concurrent deficiency or inhibition of the coagulation cascade. In these cases the bleeding diathesis is more severe than that caused by platelet dysfunction alone and may include hematoma formation or spontaneous hemorrhage into the central nervous system (CNS) or pleural or peritoneal spaces. Frequently the most obvious findings on initial examination are signs of acute or chronic blood loss anemia. Therefore identification of an underlying defect of platelet function requires an index of suspicion that a bleeding diathesis is present and a diagnostic plan for evaluating hemostatic pathways.

DIAGNOSTIC APPROACH

The initial evaluation of bleeding in dogs and cats should be directed at differentiating blood loss caused by injury to a local or focal group of vessels from a systemic bleeding diathesis. A thorough history and physical examination, in some cases including ancillary diagnostics (radiography, ultrasonography, endoscopy), is usually sufficient for locating the source and underlying cause of hemorrhage from large vessels. A history of repeated episodes of hemorrhage, bleeding at multiple sites, and concurrent disease known to affect hemostasis suggests the presence of a systemic bleeding diathesis. Preliminary screening tests should then be performed to rule out the more common bleeding disorders before one pursues detailed studies of platelet function. Table 62-1 lists screening tests of hemostasis and definitive tests for identifying platelet dysfunction.

(closure time). Although prolonged PFA-100 closure time is compatible with platelet dysfunction or vWD, nonspecific prolongation of closure time also occurs in patients with thrombocytopenia, anemia, drug therapy, and disorders that affect blood viscosity (Mischke and Keidel, 2002).

Specific Platelet Function Testing

Platelet response and specific platelet defects are characterized by performing a series of in vitro tests to evaluate platelet structure and function (see Table 62-1). Test procedures and reagents must be adapted and validated for use in dogs and cats to accommodate species-specific differences. Accurate measurement of platelet function in aggregation and release studies requires that samples be analyzed within 3 hours of collection to ensure the viability of patient platelets. This requirement necessitates patient referral to the clinic or center where testing is performed. Platelet aggregation in response to different agonist compounds is measured by detecting changes in light transmission of platelet-rich plasma samples or changes in electrical impedance of whole blood samples. Whole-blood aggregation studies use small sample volume and are simple to perform, features useful for detecting dysfunction in patients that have acquired disorders secondary to disease or drug administration. Aggregation studies that use platelet-rich plasma (PRP) are difficult to perform, but they provide more detailed information for characterizing and defining platelet response in patients having inherited platelet function defects. Flow cytometry can be used to assess platelet membrane GP composition and activation response, with the potential advantage of small sample volumes. Special platelet function testing is available at our laboratory and at other veterinary teaching hospitals (including Auburn University and the University of Pennsylvania).

SPECIFIC DISORDERS

Acquired Platelet Dysfunction

Platelet dysfunction occurs in association with many common disease conditions and drug therapies. The clinical significance of impaired platelet function is highly variable under these conditions. The clinician should be prepared to closely monitor and, if needed, treat patients with hemorrhagic complications. Conversely, if hemorrhage caused by platelet dysfunction is suspected, a thorough search to identify underlying disorders or drug administration is indicated.

Platelet Dysfunction Secondary to Disease

The disorders most commonly associated with platelet dysfunction are listed in Box 62-1. Complex and variable patterns of abnormalities are often seen in platelet function studies of these patients, and the mechanisms underlying platelet dysfunction are likely to be multifactorial. Factors extrinsic to the platelet may predominate, such as impairment of platelet adhesion caused by changes in blood viscosity in anemic patients or the presence of paraproteinemia. Uremia is believed to cause an intrinsic platelet function defect by altering PG

Box 62-1

Diseases Associated With Acquired Platelet Dysfunction

- Anemia

- Uremia

metabolism, in addition to an extrinsic defect related to an increase in plasma levels of dialyzable metabolites.

Platelet Dysfunction Secondary to Drug Administration

Many drugs demonstrate platelet inhibitory effects in vitro; however, clinically significant impairment of hemostasis has been reported for relatively few of these products. Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) are most commonly implicated in cases of drug-induced platelet dysfunction in dogs and cats. These drugs block production of thromboxane, a potent platelet agonist, by inactivating platelet cyclooxygenase. The effects of aspirin on platelet function are irreversible, lasting as long as 7 days; whereas inhibition caused by NSAIDs is transient, lasting for only a few hours (Grauer et al, 1992). The drugs listed in Table 62-2 have proven or

[¶] Interferes with the rise of intraplatelet calcium levels.

potential platelet inhibitory effects and should be used cautiously, if at all, in patients undergoing surgery or demonstrating signs of abnormal hemostasis.

Inherited Platelet Dysfunction

Inherited disorders of platelet function can be classified broadly into disorders of platelet membrane GPs, defects involving platelet storage granules, defects of intracellular signaling, or lack of platelet procoagulant activity (Kottke-Marchant and Corcoran, 2002). Inherited platelet defects are rare and often breed specific (Table 62-3). Affected dogs and cats may be maintained as pets provided that they are managed carefully, with transfusion therapy as needed for bleeding crises.

TREATMENT OF PLATELET DYSFUNCTION

Effective treatment of platelet dysfunction includes control of hemorrhage from the sites of active bleeding, stabilization of the patient to ameliorate signs of hypovolemia or blood loss, and correction of any underlying disease that may cause or exacerbate the hemostatic defect. Acquired platelet dysfunction is far more common than inherited platelet disorders, and the long-term management of dogs and cats with acquired disorders is dictated by the specific primary disease process (see Box 62-1). Initial treatment for both acquired and inherited disorders can be divided into transfusion and nontransfusion support.

Transfusion Therapy

In contrast to management of thrombocytopenic patients, limited transfusion support is often effective in controlling hemorrhage caused by platelet dysfunction. The physical presence and any residual function of thrombopathic platelets enable them to participate in the formation of hemostatic plugs initiated by the normal, transfused platelets.

Blood Collection and Processing for Platelet Transfusions

Blood products that supply active platelets include fresh whole blood (FWB), PRP, and platelet concentrates (PCs). Special collection and processing techniques are needed to maintain maximal platelet viability and prevent the formation of platelet aggregates (Mooney, 1992). The most important of these include (1) maintenance of blood products at room temperature throughout collection, processing, and storage; (2) use of plastic bags or syringes and citrate-based anticoagulants rather than glass receptacles and heparin anticoagulant; and (3) transfusion within 24 hours of collection (FWB) or within 3 days (PRP, PCs). Special care is given to aseptic collection technique because platelet transfusions are maintained at room temperature. It is ideal to administer these products as soon as possible after collection.

PRP is prepared by centrifugation of FWB for less time and at a lower speed (soft spin) than routinely used for separation of fresh plasma. Platelets remain suspended in the supernatant plasma, with an expected yield of about 80% of the platelets in whole blood. Platelet concentrates are prepared by centrifugation of PRP using a high speed (hard spin) to form a platelet pellet and then suspending the pellet in a small volume (50 to 75 ml) of plasma (Abrams-Ogg et al., 1993). The PRP and PCs prepared in this manner have some contamination with donor red and white blood cells, albeit at a much lower concentration than that of the whole blood from which they are prepared. The equipment and supplies for production of PRP and PCs are readily adapted for dogs, but the short storage life of these products limits their use primarily to the referral centers where they are prepared. Transfusion of platelet components in feline medicine has been reported only in research rather than clinical settings.

Guidelines for Platelet Transfusion

Donor selection. Donors should be blood-type compatible with recipients because all platelet replacement

Table 62-3

Hereditary Platelet Function Defects*

Type Defect	Reported Breeds	Laboratory Features
Thrombasthenia	Otter hound, Great Pyrenees	Abnormal adhesion and clot retraction, aggregation failure, reduced or absent GPIIb/IIIa
Storage pool	Persian cat	Associated with Chédiak Higashi syndrome; lack of dense granules, secretion failure, abnormal aggregation, normal clot retraction
	American cocker spaniel	Dense granule number normal, abnormal ADP storage and secretion, abnormal aggregation, normal clot retraction
Signal Transduction	Basset hound	Abnormal adhesion and aggregation, abnormal cAMP metabolism, normal clot retraction
	Spitz	Abnormal adhesion and aggregation, abnormal signaling pathway, normal clot retraction
Platelet procoagulant activity	German shepherd	Normal aggregation and secretion, normal clot retraction, abnormal prothrombinase activity, abnormal PS externalization and microvesiculation
Complex or Undefined Defects	Collie	Associated with cyclic neutropenia, partial aggregation defect, abnormal uptake and storage of serotonin, abnormal protein phosphorylation
	Boxer	Abnormal aggregation to ADP and collagen

ADP, Adenosine diphosphate; cAMP, cyclic adenosine monophosphate; PS, phosphatidylserine.

* Clinical severity ranges from mild-to-severe bleeding tendency.

products (FWB, PRP, PCs) contain red cells. Feline donors and recipients should be matched for blood type A or B, whereas dogs negative for DEA 1.1 and DEA 1.2 (see Chapter 56) can be used as universal donors for platelets. Greyhounds are not recommended as donors for production of PRP because it is difficult to obtain high yields of their platelets with the use of routine centrifugation protocols. Recipients likely to need repeated transfusions over long periods of time (months) are at risk for developing alloantibodies to foreign platelet antigens. Sequential donations from a single donor rather than pooled platelet donations are likely to delay the immunization process (Slichter et al., 1986).

Platelet administration. Intravenous catheters should be placed in peripheral veins of thrombopathic patients because catheterization of the jugular vein might cause perivascular hemorrhage and interfere with respiration. If intravenous catheter placement is impossible, transfusion via the intraosseous route is an acceptable alternative for platelet replacement. Intraperitoneal transfusion and intraoperative salvage of blood are not effective means of supplying active platelets. In-line blood filters should be used for FWB and platelet component transfusions. An appropriate rate for transfusion is 6 ml/min for dogs, with the transfusion completed over the period of 1 to 2 hours for both dogs and cats. Routine pretreatment with corticosteroid or antihistamine is not required.

Clinical indications. Platelet transfusion is always indicated to provide rapid control of hemorrhage in critical functional sites such as the CNS or respiratory tract. A single transfusion is often sufficient to control epistaxis or other mucosal hemorrhage, whereas transfusion support for patients undergoing surgery is more intensive. A first transfusion is given before surgery, within 1 to 2 hours of the procedure. A second dose is given after surgery for major surgery or if any excess hemorrhage is noted. Close monitoring of the surgical site and serial determinations of hematocrit should be performed for the first 24 hours after surgery, and an additional platelet transfusion given if required. It is unusual for rebleeding to occur if hemostasis is adequate at 24 hours after surgery. The BMBT is not an accurate predictor of perioperative bleeding complications.

FWB is the optimal product for treating thrombopathic dogs or cats having signs of acute blood loss anemia and active hemorrhage. Platelet components (PRP, PCs) are ideal for preoperative prophylaxis and for thrombopathic patients requiring repeated transfusion within a 24-hour period. Platelet concentrates provide most of the active platelets, in less than one half the volume, of the PRP from which they are prepared. Nevertheless, transfusion of PRP is usually sufficient to supply effective numbers of platelets without volume overload, and the extra time and expense in preparing PCs is rarely worthwhile when one treats acquired or inherited platelet dysfunction. Table 62-4 presents general dosage guidelines for platelet replacement. The most successful transfusion strategy is to treat with an initial high dose of blood products to supply enough active platelets for hemostatic plug formation.

Table 62-4

Guidelines for Platelet Transfusion

Product	Dose	Frequency
Fresh whole blood	12 to 20 ml/kg	q24h (volume overload limits interval)
Platelet-rich plasma	5 to 10 ml/kg	q6-12hr
Platelet concentrate	1 unit */15 kg	q6-12hr

*One unit is defined as the platelet concentrate produced from 450 ml of fresh whole blood.

Transfusion Reactions

Transfusion of platelet products may be complicated by any of the acute, chronic, immune, or nonimmune reactions associated with transfusion of whole blood. Acute reactions are treated by stopping the transfusion and administering symptomatic or supportive care. Febrile reactions are the most common complication. These reactions tend to be self-limiting and are probably mediated by white blood cells in the platelet products. Procedures for removing contaminant white blood cells (special centrifugation techniques, leukocyte filters) also reduce platelet yield. Urticaria and anaphylaxis are uncommon acute immune transfusion reactions. Urticaria may be a reaction to plasma proteins; this condition is treated with administration of antihistamine and short-acting corticosteroid. Anaphylaxis may result from transfusion of incompatible red blood cells or transfusion of large aggregates of activated platelets. These complications are prevented with the use of only type- and crossmatch-compatible platelet donors, careful collection techniques, and transfusion through blood filters. Dogs that receive repeated transfusions throughout their lives are at greatest risk for alloimmunization, causing shortened survival of transfused donor platelets. Posttransfusion purpura refers to an immune thrombocytopenia in a recipient caused by the development of high titer alloantibodies that cross-react with the recipients' platelet antigens.

Nontransfusion Therapy and Supportive Care

No drug or hormonal therapy can substitute for the structural and metabolic roles of platelets in initiating primary hemostasis. In human medicine desmopressin acetate (DDAVP; 1-deamino[8-D-arginine] vasopressin) is used as adjuvant therapy for patients with mild or nonspecific signs of defective primary hemostasis. This drug may be applicable for the treatment of dogs and cats, but there are no controlled studies demonstrating clinical efficacy.

For secondary or drug-induced platelet dysfunction, treatment of the underlying disorder or discontinuation of the suspected drug may be sufficient to prevent or control hemorrhage and obviate the need for transfusion. In these cases invasive procedures should be avoided or delayed, pending the response to specific treatment.

Local treatment of surgical or traumatic wounds can eliminate or reduce the transfusion requirements

of thrombopathic patients. Procedures for improving local hemostasis include electrocautery, ligation of small vessels, multilayer closure of incisions, and application of pressure wraps. Topical tissue adhesives are very effective in controlling hemorrhage from small wounds on cutaneous or mucosal surfaces, provided that bleeding is first controlled with direct pressure and the tissues are dry. Oral tissues are rich in fibrinolysins and are likely to bleed. To minimize hemorrhage from gingival injuries and tooth extraction sites, these wounds can be packed with absorbable sponges and sutured.

CHAPTER 63

Clinical Trials in Veterinary Oncology

CHAND KHANNA, *Bethesda, Maryland*
MELISSA PAOLONI, *Bethesda, Maryland*

Clinical trials in veterinary oncology are growing in scope and importance. Trials that evaluate novel therapies for dogs and cats with cancer have the opportunity to improve the outcome and quality of life for veterinary patients, as well as human patients with cancer. The demand for clinical trials has been fueled by the rapid increase in the number of pet animals treated for cancer and the pet-owning public's interest in effective and well-tolerated treatments for their companions. Interest from the human cancer drug development industry is based on a need for more reliable ways to evaluate new cancer drugs and the strong similarities established between veterinary and human cancers. Accordingly, well-designed clinical trials in veterinary oncology offer the opportunity to develop new drugs in both species. Interestingly the clinical outcome for patients who are managed within a clinical trial has consistently been shown to be superior to use of the same agents outside the

setting of a clinical study. This suggests the value of clinical trials not only to future patient care but also to the actual patient involved in a study. Through the conduct of clinical trials our opportunities to prevent, diagnose, and treat cancer will continue to improve. This requires greater direct and indirect participation from both primary care veterinarians and veterinary specialists.

TRIAL DESIGNS

Clinical trials aim to answer specific scientific questions to find better ways to improve care for patients with cancer. The first step in the design of a clinical trial is to articulate the questions that the trial should address. Generally this is done by asking: what is the primary study objective? Based on a combination of primary and secondary objectives, investigators define the optimal trial design for a specific study. There are three general types of clinical trials: ther-

apeutic, prevention, and screening. Irrespective of the intent of the trial, clinical trials are prospectively conducted.

Therapeutic Trials

Therapeutic trials test new therapies such as new drugs, radiation protocols, combination therapies, or novel modalities such as gene therapy or cancer vaccines.

Prevention Trials

Prevention trials assess new approaches to reduce the risk of developing certain types of cancer. These are less common in veterinary medicine but can be thought of as those that involve lifestyle changes for pets such as diet changes or supplement administration. In the future these trials may assess the ability of an intervention to reduce the risk of cancer development in a high-risk animal (i.e., breeds at high risk for specific cancers).

Screening Trials

Screening trials evaluate novel tests that diagnose or define the stage of a cancer. These tests may involve new imaging techniques such as positron emission tomography, magnetic resonance imaging, or new molecular tests such as polymerase chain reaction to confirm a diagnosis of leukemia in a patient with lymphocytosis.

Retrospective Studies

Trial designs described below are distinctly different from retrospective studies that are commonly seen in the veterinary literature. Retrospective studies are those in which patients have already received a specified treatment or undergone a specific test from which data in their medical records are collected for analysis. Retrospective trials are particularly inferior when assessing the benefits of one therapy over another.

Prospective Trials

Prospective trials involve the deliberate design of a clinical trial intended to answer a specific objective or ques-

tion. Patients are entered into this trial and managed within the constraints of a carefully designed study protocol. A protocol provides the background, specifies the objectives, and describes the design/organization of the trial. The value of this careful protocol design ensures the accuracy and consistency of results that come from clinical studies and provides an opportunity to verify and validate results. In general, the results from prospective clinical trials are considered to be more valuable than results from retrospective studies. Prospective trials are those most likely to make inferences about effectiveness of a new treatment. It is these trials that will be the basis of subsequent discussion.

PHASES OF CLINICAL TRIALS

Most clinical research in human oncology is very well defined, and the testing of new therapies proceeds in a stepwise process. Clinical trials are broken up into three phases so that the questions they answer are distinct. Table 63-1 outlines the most traditional phases. Although the named phases of clinical trials are not always used in veterinary oncology trials, many veterinary studies aim to answer the same questions of safety, efficacy, and comparison to conventional therapy.

RANDOMIZATION AND STRATIFICATION

Randomization is the process of assigning patients to a treatment group within a clinical trial by chance instead of choice. Treatment groups may include the standard of care, the standard of care plus a new therapy, a new therapy alone, or in some cases a placebo. The goal of randomization is to reduce bias (i.e., influence) for known and unknown characteristics (e.g., age, stage of disease, previous treatments) that may influence a response to the study therapy. Randomization tends to produce comparable treatment groups in terms of factors (i.e., confounders), not necessarily part of a study, that may affect a treatment outcome. Depending on the study, group randomization may be balanced 1:1, in which a patient has an equal chance of assignment to one study group over another, or skewed. Skewed or weighted randomization strategies can allow more patients to enter one group versus another. This strategy is most often used in placebo-

Table 63-1

Phases of Clinical Trials

	Phase I	Phase II	Phase III
Aim	Toxicity Dose finding	Efficacy/Responding histologies	Comparison to standard of care
Patient Number	Small	Large	Large
Dose	Escalating in cohorts	Fixed	Fixed
Single therapy	Yes	Yes or No*	Yes or no*
Randomization	No	Yes or No	Yes

*Can be combination therapy.
Phase I trials define a maximally tolerated dose of a new drug/regimen through dose escalation. In this trial toxicities associated with the new therapy can be defined. If a phase 1 trial is successful, its discovered dose moves into a phase II trial to assess efficacy and identify responding histologies. Phase III trials enroll larger number of patients to compare the dose of the new therapy to standard-of-care treatment. Phase III trials can also assess if a new treatment is less toxic or less expensive with equal/improved efficacy to current standards.

controlled studies in which a 4:1 randomization structure would result in four dogs randomized to receive the active treatment for every one dog that receives a placebo. During treatment, assessment, or follow-up it is common for the randomization of patients to be “blinded” or left unknown to participants, investigators, and statisticians. Historical controls are confounded by many variables that cannot be balanced between groups. These confounding variables may include differences in patient diagnosis, selection for a treatment, or the type of follow-up provided to patients. These variables may influence outcome to a greater extent than the treatment itself.

In some cases a patient characteristic (e.g., age, breed, past treatment, stage) is known or suspected to have an effect on the outcome of patients included in a clinical trial. For example, dogs with T-cell lymphoma are known to have a poorer outcome compared to dogs with B-cell lymphoma. To ensure that this variable is equally distributed across treatment groups, the strategy of *stratification* of dogs for these known prognostic variables occurs before randomization (Fig. 63-1).

END POINTS

Common end points in clinical trials include safety/toxicity and efficacy. Criteria for *safety* and *toxicity* have recently been established for veterinary patients through the Veterinary Cooperative Oncology Group. These published guidelines list a number of adverse events that may be noted in the evaluation of an animal in a clinical trial and allow the categorization of the severity of these events on a grade from I (least severe) to V (most severe—related

to death). These guidelines allow consistency in the reporting of safety/toxicity end points in clinical trials. Activity of a new cancer agent can be measured in several ways, including *response rate* in measurable/macrosopic disease, *disease or progression free interval* (DFI/PFI), *overall survival*, and *quality of life* (QOL). Biologic end points such as pharmacokinetic and pharmacodynamic assessments are also becoming increasingly important in veterinary oncology clinical trials. These biologic end points have been incorporated into study designs to better understand the mechanism of novel therapies/interventions. End points differ, depending on the type and objectives of a study, and are defined prospectively in the study protocol.

POWER

The *power* of a study is a measure of its ability to identify statistically significant differences between treatment groups. If the difference between treatment groups is small, the number of patients needed to be included in a trial needs to be large. The size of the patient population is a primary determinant of the power of a study. The calculation of sample size using a power analysis should be conducted before the initiation of a study. Increasing the statistical power in a study strengthens the chance of finding a statistically significant result when there is one. Veterinary trials are commonly underpowered and may be reported as “non-significant” even when there is a clear “trend” towards efficacy. Sometimes, simply increasing the number of study animals in each treatment group can lead to demonstration of both statistical and clinical significance of a treatment.

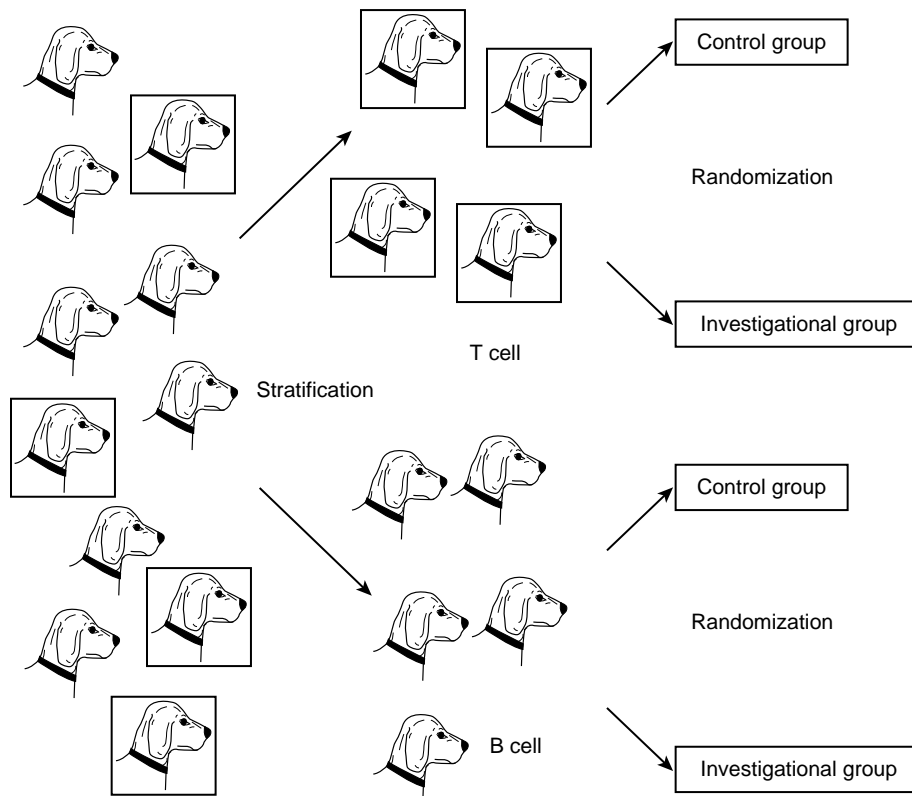

Fig. 63-1 Stratification can prevent potential bias from known prognostic factors such as immunophenotype in canine lymphoma. For example, it may appear that a treatment arm is doing poorly, thus concluding that the treatment is ineffective. But this cohort had a majority of dogs with T-cell lymphoma. Therefore the immunophenotype effect could mask the would-be positive benefits of the new therapy. Stratifying dogs by immunophenotype before randomization would allow researchers to look at separate subgroups and see if differences exist between “equal” treatment and control arms.

ETHICAL CONSIDERATIONS

There are key ethical standards used in clinical trial design, and it is the goal of all clinicians to ensure that these standards are met when presenting the option of a trial to a client or enrolling a patient in a clinical trial. The motivation for clients to enter clinical trials includes the lack of treatments currently effective for their pet's cancer, side effects that may limit their interest in pursuing conventional treatments, and the high costs of many cancer therapies. For the most part, clinical trials are provided at no or limited cost to clients. It is increasingly important to include the option of clinical trials when presenting the medical options available for a specific patient. In many cases owners' motivation to choose a clinical trial is influenced by their desire to help their pet and to improve outcomes for future pets or people with cancer.

Informed consent is required for all patients to enroll in a clinical trial. This is a written acknowledgement created by a trial's principal investigators, signed by a client, of the possible positive benefit and conversely the *adverse effects* of participating in a clinical trial. This informed consent defines the purpose of the trial and the requirements of the client to return with the pet for future follow-up procedures/appointments. Adverse events outside of those described are always possible; informed consent ensures that clients understand that in many trials the outcome/adverse effects are yet unknown.

It is important to protect all patients that enter clinical trials from expected and unexpected harm. *Stopping rules* within a trial protocol are used to remove participants in a trial if severe side effects are seen or if there is evidence that the patient's cancer is progressing in the face of treatment. If a patient fails to respond or progresses while in one treatment arm, it can be possible to *cross over* into another treatment arm. In addition to stopping rules for patients in a trial, the entire trial might also be stopped prematurely if there is strong evidence that the new intervention/agent is very effective or if the overall incidence of side effects is higher than expected. More recent innovative trial designs, referred to as Bayesian or outcome-adaptive randomization trials, assign more patients to the treatment arm that appears to be most effective. The increased use of such adaptive trials increases the benefit and reduces side effects for all participants in a trial. *Compassionate use* of an investigational agent is a mechanism for patients to continue on a therapy or have access to a therapy outside of the original clinical trial objectives or design. Collectively these measures ensure that a patient's best interests are maintained during their participation in a trial.

PRACTITIONER INVOLVEMENT IN CLINICAL TRIALS

The active engagement of veterinary general practitioners in conducting oncology clinical trials is integral to their success. These clinicians are the first to recognize and diagnose cancer in companion animals, and can act as the front line for education of clients regarding the availability of clinical trials. This information should be one of the options available to a family. Reassuring clients about the myriad of treatment options available today to pets with cancer and removing the mystery surrounding clinical trials is one of the most important concepts in developing new techniques to fight cancer in companion animals. It is also proven that involving patients in clinical trials provides the best care to patients in both the short and long term.

Clinical trials are often conducted through academic veterinary teaching hospitals or referral centers and increasingly include direct involvement from private practitioners. Patients may not be able to return to tertiary care centers for recheck examinations; thus these are often handled locally by their referring veterinarians. The timely reporting of these rechecks to the study center site and accurate record keeping are necessary for the reporting of clinical trial results, which include all possible long-term adverse events (side effects) from a new therapy, as well as outcome data.

Collection of Specimens for Cytology

KENITA S. ROGERS, *College Station, Texas*

The usefulness of cytology as a diagnostic tool is well established. Evaluation of high-quality cytology preparations can provide a definitive diagnosis in many cases and may at least provide powerful supportive evidence of a disease process in others. Cytology can play an important role in establishing a prognosis, as well as guiding further diagnostic and therapeutic decisions. Collection of representative cells from a lesion or organ remains the quality-limiting step of this important technique. Poor-quality samples even have the potential to be quite misleading in the diagnostic workup and can prompt inappropriate therapy. This chapter focuses on cellular collection techniques, necessary supplies, appropriate slide preparation methods, and problems that may arise during this process.

Indications for cytologic evaluation include a palpable external mass, swelling, or ulceration; mass lesions arising from an internal organ; irregularity in an organ within the thoracic or abdominal cavity noted by physical examination or imaging techniques; organomegaly, including lymph nodes, liver, spleen, prostate, or kidneys; or fluid accumulation in body cavities, including joints, peritoneum, pleura, or pericardium. Cytology can also be used to assess for inflammation or tumor infiltration in organs that are grossly normal on examination. Because of its immediacy, cytology can be used effectively to help with decision making in the intraoperative setting.

The basic supplies required for sample collection are listed in Box 64-1. Whereas 1- to 1.5-inch needles are adequate for many clinical cases, longer spinal needles are often required for intracavitary aspirates to access deeper tissues. The recommended needle size varies with the tissue type and expected exfoliation. Large 18- to 20-gauge needles may be needed for lesions that are unlikely to exfoliate well such as bone aspirates, whereas most lesions and organs can be aspirated adequately with 21- to 25-gauge needles. The recommended syringe size is typically between 6 and 12 cc, which provides adequate suction and also is a comfortable fit for the operator's hands.

METHODS OF CELL COLLECTION

The technique recommended for collecting cytologic specimens varies, depending on lesion location, expected tissue characteristics, and patient restraint issues. No skin preparation is needed for external lesions or lymph nodes; but, if a body cavity is to be penetrated, surgical preparation of the skin is required. The area to be penetrated by the needle is small; thus extensive shaving is not necessary.

Imprints

The simplest method to collect cells is to directly imprint tissues onto a glass slide. This is an effective technique for biopsy specimens from organs or masses that exfoliate well. Blood and tissue fluid is blotted from the cut surface of the specimen, which is subsequently touched to the surface of a clean glass slide. Depending on the size of the specimen, several imprints may be made per slide. If the biopsy was retrieved as a small core, the specimen can be gently rolled down the slide with a small-gauge needle, avoiding crushing or fragmenting the biopsy. Imprinting may also be used to collect cells from discharges, typically from the nasal or vaginal cavities or external ulcers. Although easily accomplished, imprinting discharge fluid or an ulcerated surface often collects superficial inflammation, dysplastic cells, and contaminating bacteria, which may not be representative of the underlying disease process. For a superficial lesion or discharge, a glass slide is impressed directly to the lesion to collect material. If the material appears to be too thick, horizontal or vertical pull-apart smears can be made to ensure that some areas are thin enough for evaluation (see section on Slide Preparation later in the chapter). Swabs may be used to collect cells from fistulous tracts; ear canals; or the vaginal, nasal, or respiratory tracts. A sterile cotton swab or biopsy brush is used to collect cells from these sites and is then rolled down the length of the slide.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is preferred for cell collection from mass lesions and organs. It avoids superficial contamination and is more likely than imprinted specimens to be representative since several adjacent areas can be aspirated. The classic method of cellular collection involves piercing a mass or organ with a needle (21- to 25-gauge) that is attached to an empty syringe (6 to 12 cc). A 4- to 8-cc amount of suction is placed on the syringe to create a pressure vacuum that encourages cells to dislodge and move into the needle. With pressure held, the needle can be moved in different directions within the mass. If the aspirated site is intraabdominal, the risk of hemorrhage may be slightly increased with repeated needle redirection, and it is often recommended that the area be examined with ultrasound following the procedure to note any evidence of continued bleeding from the site. Redirection of the needle is not recommended with lung aspirates because of the risk of developing clinically

Box 64-1

List of Supplies Required for Basic Cytologic Collection Techniques

- Clean, dust-free glass slides
- 6- to 12-cc syringes
- Variety of 1- to 1.5-inch needles (20- to 25-gauge needles)
- 2.5- to 3.5-inch spinal needle with stylet
- Scalpel blades (Nos. 10 and 11)
- Romanowsky-type stain: Diff-Quik
- Slide dryer
- Marker for identifying slides
- Ethylenediaminetetraacetic acid (purple top) and serum (red top) tubes

significant pneumothorax. When aspiration has been completed, pressure is released, and the needle and syringe are withdrawn from the lesion. The cells collected typically are within the needle, and there may be no visible material within the syringe. Indeed, if material or blood is noted within the syringe, suction should be released, and the aspiration technique stopped. The needle is disconnected from the syringe, which is subsequently filled with air. After reattaching the air-filled syringe to the needle and holding the tip close to the slide, air is expelled through the needle to push material onto an appropriate area of the glass slide. Aspiration is facilitated by immobilization of the mass while the aspiration occurs. One helpful method is to hold a palpable mass between the thumb and index finger of the left hand with the palm up (for the right-handed clinician). This leaves the remaining fingers and palm free to grasp the barrel of the syringe while the right hand is used to apply suction.

Coring Technique

To avoid the cellular disruption that can be caused by the pressure of aspiration, the coring technique uses only a needle to collect cells. The needle is advanced through the mass or organ and is redirected several times for the purpose of dislodging cells and causing them to be driven into the hollow shaft of the needle. After the needle has been removed from the lesion, an air-filled syringe is used to expel the contents of the needle onto a slide similar to FNA. Alternatively, an air-filled syringe can already be attached to the needle, expediting the process. The coring technique diminishes blood contamination of the specimen in vascular tissues; and there is better control of needle placement, which is particularly useful for ultrasound-guided collections.

Scraping

Although FNA and coring are excellent methods for collecting cells from masses that exfoliate well, some types of tissue are very compact and do not readily release cells by these techniques. For these situations a scalpel blade or spatula can be used on the lesion or biopsy specimen to scrape across the surface several times and remove a small portion of the tissue. This fragment is placed on

the proximal end of the slide and then spread as thinly as possible over the remainder of the slide by the blade or a second slide. There remain some tissues such as tumors of fibrous connective tissue origin that have cellular adhesion characteristics that do not allow the cells to be spread adequately over the slide for cytologic evaluation; for these specimens histopathology is required for definitive diagnosis. For superficial ulcerative lesions such as squamous cell carcinoma (SCC), a scraping may be used to collect cells below the ulcerated surface. In this case representative cells may have been difficult to collect with FNA because of the thin layer of tumor cells that characterizes some SCCs. Scraping collects a large amount of material; but, like imprints, if the collected cells are too superficial, they may not be representative of the underlying disease process.

Intracavitary Collection

FNA and the coring technique can be performed on mass lesions within the thoracic, peritoneal, or pericardial cavities. Differences in technique include the need to clip a small area of hair and perform a surgical preparation of the area. In addition, the animal must be well restrained, and in some cases sedation is necessary. Additional risks may be encountered with intracavitary aspirates. These include hemorrhage, which is usually minor and self-limiting, and the risk of rupturing an abscess or neoplasm that may spill into and contaminate a body cavity. Pneumothorax is an important potential complication when performing lung FNA. Use of small-gauge needles and appropriate patient selection can diminish this risk. Patients that are significantly tachypneic or in respiratory distress have a higher complication rate with this procedure, and fractious animals should be sedated to avoid unnecessary movement. The risk of pneumothorax is small when aspirating cranial mediastinal masses because the lungs are pushed caudally. Lung aspirates are most rewarding with diffuse infiltrative disease or large focal lesions. Many primary lung tumors have necrotic centers; thus recovery of only inflammatory material from a lung mass does not rule out neoplasia. Although intracavitary lesions can be aspirated based on triangulation techniques or mass palpation, ultrasound guidance improves the accuracy of cellular recovery. Blood contamination is a particularly common problem with joint aspirates. The use of small-gauge needles, gentle aspiration with no redirection of the needle, and patience as the viscous fluid is collected are helpful. If the disease process appears multifocal, multiple joints should be aspirated.

SLIDE PREPARATION

The quality of the slide depends not only on the number of cells collected but the percentage of cells that remain intact and available for microscopic evaluation. Artifactual cell rupturing and cellular distribution on the slides can be affected greatly by the techniques used in slide preparation. Smears should be made immediately after the material has been placed on the slide. If a large amount of material is collected, placing a portion on more than one slide helps avoid preparations that are too thick.

Having too much material on a slide initially greatly diminishes the chance of spreading it into a monolayer that can be easily assessed microscopically. Making multiple slides increases the chance of obtaining a diagnostic sample. In addition, material that is placed near the end or edges of a slide may be difficult to bring into focus at different magnifications. The ultimate goal is to have a well-prepared slide with many intact, representative cells. A description of the two most common slide preparation techniques follows.

Making Smears

Cells from lesions or organs that are deemed to be fragile can best be prepared using the *vertical pull-apart* technique (Fig. 64-1). The cells collected within the needle are pushed onto the center of the first slide. The center of the second slide is gently placed at right angles directly down on the cellular material, which then spreads between the slides. If the material is too thick, very gentle compression of the slides may be necessary. With as little rotational motion or shear force as possible, the two slides should be separated vertically; the material is likely to be fairly evenly distributed between the two slides, providing mirror images of the cytology preparation. This technique is often required for fragile tissues such as lymph nodes, and it is particularly useful when lymphoma is suspected since malignant lymphocytes are often even more fragile than healthy normal lymphocytes. A potential negative outcome of preparing a vertical pull-apart slide is that cells are not allowed to separate as well as with other methods and many areas may be too thick to evaluate properly. This can result in particular difficulty in differentiating cells that are truly clustering (epithelial origin) from cells that are simply very close together because of the method of slide preparation, thereby leading to confusion regarding the type of tumor represented on the slide.

Most tissues have cells that can withstand some degree of shear force and trauma in preparation without causing widespread cellular disruption. These samples and materials collected by scraping or other thick preparations should be prepared by *horizontal pull-apart* techniques (Fig. 64-2). In this case cells are pushed from the needle

Fig. 64-1 Technique for making vertical pull-apart slides. The stained specimen on the right represents a properly prepared vertical pull-apart slide.

Fig. 64-2 Technique for making horizontal pull-apart slides. The stained specimen on the right represents a properly prepared horizontal pull-apart slide.

onto one end of the slide. The second slide is used to smear the cellular material along the length of the first slide in a continuous motion, with the flat surfaces of the slides remaining parallel to one another. In most cases the majority of the cellular material remains with the first slide. One form of a horizontal preparation is the technique used to make a blood smear. A small drop of thin fluid is placed at one end of the slide while a second slide is pulled backward at a 45-degree angle to touch the drop, which spreads along the surface of contact. The second slide is advanced immediately, spreading the cellular material along the length of the first slide. The advantage of a horizontal preparation is that the cells are spread more thinly over the length of the slide and there is less confusion regarding the spatial relationship of the cells to one another. The most important disadvantage is a greater risk of cellular rupture.

After collection of a fluid sample (pleural, pericardial, peritoneal, or joint effusions; transtracheal wash; bronchoalveolar lavage; peritoneal lavage; prostatic or bladder wash), aliquots should immediately be placed in ethylenediaminetetraacetic acid tubes to prevent clotting and appropriately collected for culture and sensitivity testing if indicated. Cytologic smears should be made quickly after fluid collection. Direct smears are made from well-mixed fluid or alternatively from the spun pellet of cells after centrifugation. The slide made from a drop of the fluid or sediment can be prepared vertically, horizontally, or similar to blood smear preparation.

Fixation and Staining

Ideally, when several slides are made, a few should remain unstained in the event that special procedures are required at a later time. The most common cytologic stains used in the practice setting are Romanowsky-type stains such as Diff-Quik and occasionally new methylene blue. Although new methylene blue provides wonderful nuclear detail, the visual aesthetics, practicality, and permanence of the Romanowsky-type stains make them the most useful agents for routine cytology. They are inexpensive, easily obtained, and simple to use. These polychromatic stains highlight organisms and cytoplasm very well, and nuclear and nucleolar detail is usually adequate

for assessing inflammation, neoplasia, and characteristics of malignancy. Smears must first be air dried, which allows the cells to adhere to the slide. With most staining kits there are typically four individual steps. The first is fixation of the cells; lipid droplets from ruptured lipocytes often dissolve in this step. The red and blue stains follow, and then the slides are rinsed. Each manufacturer recommends specific staining procedures, but in general the thinner the smear and the lower the total protein concentration on the slide, the less time required for staining. Conversely, the thicker the preparation and the higher the total protein concentration, the more time the slide needs to remain in contact with the stain. Therefore, based on the perceived cellularity and thickness of the preparation, the clinician must adjust the amount of time used in the staining procedure. Drying the slides is important before evaluating them microscopically with oil immersion lenses. A nail dryer can be modified for use if several slides need to dry simultaneously. The patient and the site of cell collection should be clearly identified on all slides.

If cytology specimens will be submitted to an outside laboratory, all glass slides should be packaged in such a way that breakage is avoided. Steps should be taken to prevent motion of the slides, even within commercially available slide holders; a box within a box is a common approach. It is important to remember that, if cytology slides are packaged with samples for histopathology, formalin fumes can inhibit the cells from adequately taking up stain. Ideally two to three air-dried, unfixed slides and two to three stained slides should be submitted to the cytologist for evaluation.

COMMONLY ENCOUNTERED PROBLEMS

The clinician must feel comfortable that the submitted material is representative of the disease process, thus it is important for the individual collecting the material to look at slides before submission to ensure that adequate, representative material has been collected before the patient leaves the hospital. There are a variety of reasons why a slide may not contain adequate diagnostic material. Some lesions, particularly mesenchymal tumors, do not typically exfoliate well; the needle can miss the lesion, or an area of central necrosis within a tumor can be aspirated. Making several slides from multiple locations can be helpful in obtaining a representative diagnostic specimen. Excessive blood contamination can dilute tissue cells and cause clotting of the sample, make diagnosis more difficult. Using smaller-gauge needles, less aggressive aspiration, or the coring technique can help diminish blood contamination.

Poorly stained specimens can result from inadequate staining times or weakened stain from overuse or dilution. The stains may need to be changed at different intervals based on frequency of use and thickness of the specimens. In addition, the stains should be changed when unexpected contaminating organisms or cells appear on slides. It is helpful to have two separate sets of stain available, one for cytology and one for "contaminated" samples such as ear or fecal swabs. Typically the blue stain and the rinse need to be changed most frequently. If a slide needs to be restained, skip the fixative step, dip the slide a few more times in the red and blue stains, and then rinse again.

One criticism of Diff-Quik stain is that, since it does not undergo the metachromatic reaction, granules from some mast cell tumors do not stain. I have only rarely found this to be a problem in the clinical setting. However, if mast cell tumor is suspected, new methylene blue or Giemsa stain can be used to demonstrate the presence of mast cell granules.

Cellular collection and slide preparation are the first steps in using cytology as a diagnostic tool; the ability to accurately interpret what is on the slide becomes the next limiting factor. Many clinicians are extremely capable of slide interpretation, and with practice every clinician can continue to improve. One simple method of practicing these skills is to make a cytology preparation each time a biopsy specimen is submitted to the laboratory. When the histopathology report returns, results are compared, and the cytology slide reviewed again. If most cytologies are sent to a diagnostic laboratory for interpretation, developing a good working relationship with the cytologist is critical. The clinician's role is to provide high-quality specimens with accurate clinical information so that the cytologist has every opportunity to be an effective part of the diagnostic team.

INTRODUCTION TO CHEMOTHERAPY

As the only major cancer treatment modality to exert systemic effects, chemotherapy is the principal approach for treatment of systemic or metastatic malignancies. In managing chemotherapy, effective communication between the veterinarian and the pet owner is essential. Clients should understand that quality of life is the primary goal in most veterinary chemotherapy situations, and that adverse effects of chemotherapy are less severe than those seen in human patients. In veterinary chemotherapy, dose intensity is modified to avoid most unacceptable adverse effects. Of course, the definition of “unacceptable” is subjective. For some owners it may be *any* loss of quality of life, whereas for others it may be the need for hospitalization. Because quality of life for humans depends largely on preservation of body image as well as organ function, owners may interpret their pet’s well-being in similar terms. The veterinarian can help clients understand that these benchmarks are not necessarily valid for animals. When proposing chemotherapy, all therapeutic options should be presented, and the clients should be encouraged to ask questions and communicate their concerns. A continuing, open dialogue allows the client to make an informed decision and will ultimately create a “team” approach to treatment of the pet’s cancer. Supplementing verbal instructions with written information about the disease and the treatment to be used will greatly assist owners in making decisions and retaining information.

It is important to determine the goal of treatment at the outset because it often determines the course of therapy. *Cure*, the permanent eradication of all tumor cells, is an ideal outcome although not always realistic in veterinary oncology. If treatment is to be undertaken with curative intent, a greater likelihood of adverse effects may be accepted because of greater potential long-term benefit. *Palliation* is designed to improve quality of life but without expectation of cure; therefore the drug dosages and schedules used are less likely to result in adverse effects. In veterinary medicine this may result in prolonged survival because euthanasia is delayed.

Staging and Health

Before undertaking any treatment, it is important to establish the definitive diagnosis, the clinical stage of disease, and the patient’s overall health. The histologic diagnosis

and stage are important both in establishing a prognosis and prescribing a treatment plan, and prognostic information assists the client in choosing a goal of treatment. The general health screen is necessary to determine if other conditions are present that may affect the patient’s life expectancy (e.g., other systemic disease), that need to be resolved before starting chemotherapy (e.g., subclinical urinary tract infection), or that need to be taken into account in planning chemotherapy (e.g., subclinical cardiac or renal disease).

The likelihood of a successful outcome for a patient treated with chemotherapy is as dependent on drug metabolism and elimination (and drug absorption for orally administered chemotherapy) as it is on the sensitivity of the tumor. Consequently information gained during staging may identify problems that will impact the type and dosage of chemotherapy to optimize efficacy while limiting toxicity. For example, hepatic dysfunction may lead to delayed drug elimination (e.g., vinca alkaloids, doxorubicin [DOX]) and therefore greater toxicity such as myelosuppression. In contrast, cyclophosphamide is activated in the liver; thus hepatic dysfunction may result in poor efficacy. Similarly, preexisting renal dysfunction predisposes to increased toxicity of nephrotoxic drugs, whereas reduced renal excretion of carboplatin exacerbates myelosuppression.

Drug Choice

There are no strictly veterinary chemotherapy drugs. However, there is an established track record for most of the older human drugs, particularly those that have been used for the treatment of lymphoma and osteosarcoma (OSA). The body of literature available means that veterinarians should feel secure in using dosages and schedules provided in published protocols. Treatment using most veterinary drugs is expected to result in less than 20% need for dose reductions (hospitalization, severe neutropenia) and less than 5% risk of life-threatening toxicity when established dosages are used, with less than 1% risk of treatment-related mortality.

Because the costs of drug development are high, newer chemotherapeutic drugs may be quite costly. However, generic versions of many older drugs are available (vincristine, DOX, cisplatin). Some pharmacies supply small quantities of injectable drugs to veterinarians, and

compounding pharmacies reformulate smaller dosages of oral medications (e.g., lomustine [CCNU], procarbazine) for cats and small dogs.

Clinical veterinary chemotherapy research is advancing at a great rate. However, even when clinical trials are completed, it may be a year or more until the results are published. The best resources for veterinary practitioners are veterinary oncologists, the Veterinary Cancer Society (www.vetcancersociety.org), and Internet literature databases such as Medline (www.ncbi.nlm.nih.gov/entrez).

Timing of Chemotherapy

Veterinary chemotherapy protocols are often very simple, consisting of one or two agents given at an interval that minimizes the risk of toxicity but maintains the highest possible dose intensity (e.g., cisplatin as an adjuvant to surgery for dogs with OSA). In contrast, lymphoma protocols are often more complex, with many agents scheduled in combination (Table 65-1).

Primary Treatment

In veterinary oncology primary chemotherapy is usually reserved for hematopoietic tumors (LSA, leukemias, multiple myeloma). The use of chemotherapy alone for solid tumors (carcinomas and sarcomas) is rarely successful and is better considered to be palliative. The stages of a primary chemotherapy protocol can include:

Induction: Often intensely scheduled initial treatments during which a patient has a relatively higher risk of toxicity but usually also the greatest chance of response (e.g., the first 12 weeks of VELCAP).

Consolidation: Sometimes used at the end of induction using unrelated, effective drugs to further reduce the proportion of surviving cancer cells (e.g.,

mechlorethamine, Oncovin, procarbazine, prednisone [MOPP] and CCNU in VELCAP-SC).

Maintenance: A less intense (usually decreased frequency of administration) phase using drugs already used during induction. Maintenance therapy probably has little influence on whether an animal is cured or not but may prolong survival in animals by slowing the time to relapse.

Rescue: Therapy given when drugs used during the other three phases are no longer effective. Unrelated drugs, often alkylating agents because they are less likely to show cross-resistance, are used in the rescue setting.

Adjuvant Treatment

Chemotherapy can be used in combination with other modalities, including surgery, radiation therapy, or both. Adjuvant chemotherapy is used following resection of a primary tumor with significant metastatic risk to delay or prevent the progression of metastatic disease. The optimum time to administer adjuvant chemotherapy is when the metastatic disease is microscopic rather than when there are gross metastases. An example of successful adjuvant veterinary chemotherapy is the use of platinum compounds and/or DOX following surgery for canine OSA.

Chemotherapy Dosing

Most chemotherapy drugs have narrow therapeutic margins (i.e., the host toxic dose is very close to the effective dose). Therefore it is important to calculate doses as accurately as possible. Although imperfect, current dosage recommendations for most chemotherapy drugs are based on "metabolic body size" (body surface area [BSA], m²). This scheme implies that smaller animals have a higher metabolic rate and therefore should receive a higher dosage

Table 65-1

Schedule of Chemotherapy Administration for Tufts VELCAP-SC for Canine Lymphoma

Week	VCR	L-Asp	CTX	DOX	Must	Procarb	Pred	CCNU

20								X

CTX, Cyclophosphamide; DOX, doxorubicin; L-Asp, L-asparaginase; Must, mechlorethamine; Pred, prednisone; Procarb, procarbazine; VCR, vincristine. Remission is induced over 11 weeks with a combination of VCR (0.75 mg/m² IV), L-asparaginase (10,000 units/m² SQ, maximum dose 10,000 units), DOX (<1 m² = 1 mg/kg IV, >1 m² = 30 mg/m²), CTX, (200 mg/m² IV plus furosemide 2 mg/kg IV once) and a tapering dose of Pred starting at 40 mg/m² PO daily. Dogs in remission at week 13 receive consolidation treatments of MOPP (Must [3 mg/m² IV], VCR [0.5 mg/m² IV], Procarb [50 mg/m² PO daily × 14 days], and Pred [40 mg/m² PO daily × 14 days]) at weeks 13 and 14, followed by lomustine (CCNU) (60-90 mg/m² PO once) at weeks 17 and 20. Dogs that are in complete remission (CR) by week 21 discontinue chemotherapy.

on a body weight basis. For some drugs (e.g., DOX), dosage based on BSA is imperfect, and small dogs and cats should be dosed at a lower rate than large dogs. For other drugs (e.g., ifosfamide) the dosage for cats is entirely different, whereas yet other drugs (e.g., cisplatin) should be avoided altogether in cats. Until further guidelines are available, the veterinarian should check the species- and body size-specific dosing basis for any drug to be used, become familiar with the individual drugs that require a lower dosage for small pets, and use a BSA conversion table when metabolic dosing is indicated.

When oral chemotherapeutics are used, the need for accurate dosing can be confounded by the available tablet or capsule sizes, particularly in cats and small dogs. It is important to use a compounding pharmacy to reformulate oral chemotherapeutics to maintain accurate dosing for smaller pets. Tablets and capsules should never be split or opened by veterinarians or pet caregivers because it results in both inaccurate dosing and drug exposure.

The concept of *dose intensity* is an important principle of chemotherapy. It is defined as milligrams per square meter of drug per week of therapy and should be the highest tolerated by the animal with minimal toxicity. For example, in dosing of myelosuppressive drugs, because there will be variation in individual metabolism of drugs and in the sensitivity of normal tissues, the aim should be to deliver doses that produce a neutrophil nadir of between 1000 and 1500 cells per microliter. There is ample evidence in both human and veterinary oncology that optimal dose intensity improves the outcome for chemotherapy.

Drug Combinations and Drug Resistance

Combination chemotherapy has two major aims. The first is to slow the onset of drug resistance in tumor cells. The use of agents that have differing targets and mechanisms of action is most likely to provide long-term tumor control. The use of alkylating agents in combination protocols for lymphoma may slow the development of multiple drug resistance (see Section IV on Evolve). The second aim of combination chemotherapy is to maximize tumor cell kill while minimizing toxicity. Combinations that include myelosuppressive drugs with drugs that are minimally myelosuppressive may fulfill this aim (e.g., cyclophosphamide and vincristine; DOX and cisplatin). It is important that combinations use *effective* drugs; there is little point in using a nontoxic combination when one drug is not efficacious against the tumor. Therefore combinations use drugs that have activity as single agents. Some combinations may result in altered toxicity because of changes in the way a drug is metabolized or excreted. For example, L-asparaginase is thought to slow hepatic metabolism of drugs such as vincristine and DOX, thereby increasing the risk of myelosuppression. The practitioner is wise to use only combinations for which published efficacy and toxicity data are available.

Toxicity, Monitoring, and Support

Chemotherapy toxicity is usually dose related; and, because most chemotherapy drugs are effective in the active phases of the cell cycle, renewing tissues are most commonly affected.

Hematologic

Myelosuppression is a general term applied to the toxic effects of chemotherapy on the bone marrow. In veterinary clinical practice the dose-limiting aspect of myelosuppression is usually *neutropenia*. In general the prognosis for uncomplicated myelosuppression is good, and most veterinary patients recover within a few days. Most myelosuppressed dogs and cats have no clinical signs at all. The nadir (low point) of peripheral neutrophil counts occurs between 5 and 10 days after a myelosuppressive insult. Thus the usual timing for myelosuppressive drug administration is every 2 to 3 weeks. Some drugs (e.g., CCNU and carboplatin) may have delayed or prolonged nadirs, and dosing intervals may be longer for these drugs.

A complete blood count (CBC), including a platelet count, should be collected at the expected neutrophil nadir, usually 1 week after chemotherapy administration. The absolute neutrophil count (not the total leukocyte count) should be evaluated. Neutrophil recovery is usually rapid; however, a nadir of less than 1000 neutrophils per microliter should prompt a 20% to 25% dosage reduction for all subsequent administrations of that drug. It is not necessary to reduce the dosage of other myelosuppressive drugs since they may not cause the same degree of suppression. Each drug should be assessed individually. If the dose is reduced, CBC should be repeated after the next dose.

A CBC should also be assessed immediately before the next chemotherapy treatment; neutropenia is a reason to delay administration of a myelosuppressive drug (but not a nonmyelosuppressive drug such as L-asparaginase or prednisone). In general a neutrophil count of less than 3000/ μ L requires a chemotherapy delay of several days to 1 week before rechecking the CBC. If recovery is prolonged (e.g., many cats and some dogs after receiving carboplatin), it may be necessary to reduce the dosage so that the optimal intertreatment interval and dose intensity may be maintained.

Occasionally neutropenia may be severe (<500 cells per microliter) at the nadir. The risk of sepsis is low in animals that are receiving concurrent antibiotics because the nadir rarely persists for more than 2 to 3 days. Many oncologists recommend use of a prophylactic broad-spectrum, oral antibiotic (such as trimethoprim-sulfa [TMS], 15 mg/kg q12h orally [PO]) for patients receiving a myelosuppressive agent for the first time. If the nadir is more than 1500 neutrophils per microliter, subsequent administrations may be given without prophylactic antibiotics. Administration of TMS to dogs for 14 days from the day of treatment with DOX reduces the risk of gastrointestinal toxicity (vomiting or diarrhea) and hospitalization and improves quality of life. The effect is most marked in dogs with lymphoma and may be caused by reduced bacterial translocation in damaged intestinal epithelium.

When a patient is severely neutropenic, it is tempting to use recombinant granulocyte colony-stimulating factor (G-CSF). Dogs that are neutropenic have high endogenous G-CSF and are unlikely to benefit from exogenous administration. In addition, the available human recombinant product (hr-G-CSF; Neupogen, Amgen) carries a risk of inducing neutralizing and cross-reacting anticanine G-CSF antibodies. Appropriate use of hr-G-CSF would be

when an inadvertent and potentially lethal chemotherapy overdose has been delivered. For such a patient, hr-G-CSF from 24 hours after chemotherapy administration and beyond the neutrophil nadir has the best chance of preventing sepsis and death (see Section IV on Evolve for additional information about hematopoietic growth factors in oncology).

Thrombocytopenia may be dose limiting for select chemotherapy agents (carboplatin, cumulative for CCNU) but is rarely clinically significant for other drugs. Thrombocytopenia infrequently causes clinical signs; however, at counts less than 50,000/ μ L the risk of bleeding increases, and the veterinarian should be alert to petechiation, ecchymoses, or mucosal bleeding. Platelet nadirs occur later than neutrophil nadirs but are rarely as severe, and recovery is slower but usually complete. Significant thrombocytopenia in a patient scheduled to receive CCNU should prompt discontinuation.

Gastrointestinal

The gastrointestinal mucosa is another site of renewing tissue, and clinical signs include inappetence, anorexia, nausea, vomiting, or diarrhea, usually occurring 3 to 5 days following treatment. Supportive care is important in prophylaxis and treatment. In general the use of antiemetics and appetite stimulants can prevent mild toxicities. Diarrhea may be treated with dietary management, sulfasalazine, or metronidazole once specific causes have been eliminated. Chemotherapy doses should be reduced if the pet requires hospitalization for gastrointestinal signs or if such signs are unacceptable to the owner. With a 20% to 25% dosage reduction it is very unlikely that subsequent chemotherapy administration will be associated with toxicity.

Anorexia is a common side effect of chemotherapy in cats (particularly DOX or vincristine). Cyproheptadine (0.35 to 1 mg/kg PO q12-24h in cats and 0.3 to 2 mg/kg PO q12h in dogs) may stimulate appetite. Megestrol acetate is an effective appetite stimulant in cats at a dosage of 0.25 to 0.5 mg/kg daily for 3 to 5 days and then every 2 to 3 days. In humans megestrol acetate not only improves appetite but also enhances enjoyment of food. It should be used with caution in cats as it may induce diabetes mellitus.

Vincristine may result in intestinal ileus in cats and less commonly in dogs. Prokinetic drugs such as metoclopramide may prevent or reverse this toxicity. The use of prophylactic metoclopramide is recommended by some practitioners to reduce the risk of inappetence caused by vincristine and also DOX (perhaps by central action to reduce nausea). In the prophylactic setting treatment is started at the time of chemotherapy and continued for 4 to 5 days. Before administering strong emetogens such as cisplatin, owners should withhold food since this reduces the risk of vomiting and may prevent future "aversion" to that food.

The recent introduction of serotonin antagonists such as ondansetron and dolasetron has dramatically reduced gastrointestinal toxicity for animals treated with many drugs. Nausea and vomiting leading to inappetence, dehydration, and weight loss are possible following treatment with drugs such as cisplatin (in dogs) and DOX (in cats and dogs). Dolasetron (0.5 to 1 mg/kg intravenously [IV] or PO given once 20 to 30 minutes before treatment) may

markedly reduce the risk of this toxicity. A recently released veterinary product, maropitant citrate (Cerenia™, 1 mg/kg SQ q 24h) up to 5 days, a neurokinin 1 (NK1) antagonist, appears to be very effective in the prevention and treatment of nausea and vomiting in dogs given chemotherapy.

Diet should be appropriate and consistent. Prophylactic use of absorbents such as kaolin may reduce the risk of diarrhea. If diarrhea occurs, a bland diet should be offered; if it persists and other causes such as parasitism in immunocompromised patients have been eliminated, sulfasalazine or metronidazole may reduce the severity. Prophylactic TMS should be considered (see earlier discussion).

Cardiac

In veterinary oncology cardiotoxicity is only a problem clinically with DOX in dogs. Chronic cardiotoxicity is one of the few irreversible chemotherapy toxicities and carries a poor to grave prognosis. The end result resembles dilated cardiomyopathy and congestive heart failure. Injury to the conduction system also may develop. The occurrence of cardiotoxicity is related to the total cumulative dose of DOX rather than the amount of each individual dosage. Although cardiotoxicity in dogs can occur at any cumulative dosage, it is most frequent above 180 mg/m², and DOX should not be given above this level without echocardiographic monitoring. As DOX cardiotoxicity is usually progressive, treatment should be discontinued if contractility is below normal while the patient is still asymptomatic rather than waiting for signs of early cardiac failure.

Breeds susceptible to cardiomyopathy, such as the Doberman pinscher, are more susceptible to this toxicity at lower cumulative doses and should be treated with caution if at all. In dogs with valvular dysfunction, mild changes in cardiac muscle function caused by early DOX cardiotoxicity may exacerbate the clinical signs of the valvular disease. In these patients echocardiography should be performed periodically through treatment, ideally before each treatment.

The cardioprotective beta-blocker carvedilol has strong antioxidant properties and in experimental studies protects cardiomyocytes from doxorubicin-induced injury. Whether or not this treatment has clinical merit in veterinary practice requires appropriate clinical study.

Urinary Tract

Nephrotoxicity is the primary dose-limiting toxicity of cisplatin and also carries a poor prognosis. Its occurrence depends on both the individual and cumulative dosage and is dramatically reduced by pretreatment and post-treatment fluid diuresis. DOX has been anecdotally associated with nephrotoxicity in cats. Renal function should be assessed by serum creatinine and urine specific gravity before administration of nephrotoxic drugs or renally excreted drugs (carboplatin).

Urothelial toxicity (sterile hemorrhagic cystitis) is associated with cyclophosphamide and ifosfamide administration in dogs. Cyclophosphamide and ifosfamide are hepatically metabolized to their active forms and other metabolites, including acrolein. Prolonged contact between the bladder wall and acrolein results in hemorrhagic cystitis. Severity of clinical signs varies; but

stranguria, dysuria, and hematuria can be severe and prolonged over many weeks. Furosemide (2 mg/kg) given once at the time of cyclophosphamide administration almost completely abrogates this toxicity and is recommended even in dogs receiving concurrent prednisone. Allowing ample opportunity for the dog to void urine is also important, and cyclophosphamide preferably is administered in the morning rather than late in the day. This toxicity should be distinguished from infectious cystitis by bacterial culture; however, even if bacteria are isolated and signs resolve with antibiotic administration, the drug should not be administered again because infectious cystitis could have been secondary to chemical irritation. Symptomatic treatment includes antiinflammatory drugs (e.g., piroxicam 0.3 mg/kg once daily in dogs, not concurrent with corticosteroids). For prolonged cases intravesicular dimethylsulfoxide may accelerate recovery.

Hepatotoxicity

Liver enzyme serum activities (alanine aminotransferase [ALT]) should be assessed before CCNU administration. Irreversible hepatic toxicity can result if CCNU therapy is continued in the face of rising serum ALT concentrations. Elevations in serum bilirubin should also prompt dose reductions in hepatically metabolized drugs.

Soft Tissue

Whenever chemotherapy is given IV, a catheter should be used rather than a needle. Extravasation is rarely a problem if chemotherapy is administered carefully through an over-the-needle catheter placed as the first puncture in an intact vein. The catheter should be tested with a saline flush both before the drug is administered and after infusion is complete. If any drug is extravasated, as much drug as possible should be aspirated before removing the catheter. For vinca alkaloids warm compresses should be applied; for anthracyclines ice should be applied.

Hypersensitivity

Hypersensitivity reactions may occur during DOX administration as a result of histamine release from mast cells. This effect only occurs with rapid administration and is not a problem if the drug is given slowly. True anaphylaxis may occur following L-asparaginase administration, particularly by the IV or intraperitoneal route. This toxicity is rare if L-asparaginase is administered intramuscularly (IM) or subcutaneously (SQ).

Felines

Specific cat toxicities may occur with chemotherapy. Cisplatin causes a fatal, acute pulmonary edema in cats and should not be administered systemically. Any administration of 5-fluorouracil causes acute fatal neurotoxicity in cats, and products containing this drug should not be used.

SPECIFIC CHEMOTHERAPEUTIC AGENTS

Alkylating Agents

Alkylating agents create cross-links in deoxyribonucleic acid (DNA), causing strand breaks. An interesting feature of this class of drugs is the apparent lack of cross-

resistance between different alkylating agents or with other classes of drugs.

Cyclophosphamide

Used primarily for treatment of lymphoma in dogs and cats

Route: PO or IV

Dosage: Dogs 200-250 mg/m²; cats 250-300 mg/m² (see specific protocol)

Monitor: CBC

Chlorambucil

Used primarily for treatment of chronic lymphocytic leukemia or low-grade lymphoma in dogs and cats; also as a substitute for cyclophosphamide if hemorrhagic cystitis occurs

Route: PO

Dosage: Dogs and cats: 6-8 mg/m² daily for 14 days and then every other day or 15 mg/m² for 4 consecutive days repeated every 3 weeks

Monitor: Neutropenia and thrombocytopenia can occur; however, severe myelosuppression is rare at doses used in animals. Monitor CBC every 2 weeks for first 6 weeks and then every 3 months. Monitor liver enzymes (ALT) on same schedule.

Melphalan

Used primarily for treatment of multiple myeloma in dogs and cats

Route: PO

Dosage: Dogs and cats: 1.5 mg/m² alternate days or 10 days on, 10 days off (see individual protocol)

Monitor: CBC

Mechlorethamine

Used in MOPP protocol for LSA in dogs and cats

Route: IV (caution for extravasation)

Dosage: Dogs and cats: in MOPP, 3 mg/m²

Monitor: CBC

Procarbazine

Used in MOPP protocol for LSA in dogs and cats

Route: PO

Dosage: Dogs and cats: 50 mg/m² daily for 14 days or 10 mg/cat daily for 14 days

Monitor: CBC. In humans myelosuppression may occur 2-3 weeks after cessation of therapy. There is limited information for dogs and cats.

Lomustine (CCNU)

Used for treatment of lymphoma, mast cell tumors, brain tumors (responses in gliomas and meningiomas), and malignant histiocytosis

Route: PO

Dosage: Dogs: 60-90 mg/m² every 3-4 weeks or according to protocol (lower doses for small dogs); cats: 50-60 mg/m² every 4-6 weeks (reformulated)

Monitor: CBC and platelet counts immediately before and 7 days after each treatment. Leukopenia and thrombocytopenia are expected, it is dose limiting, and it may be cumulative. Platelet counts are obtained immediately before CCNU treatments because of the potential hazard of delayed, irreversible

thrombocytopenia. Serum ALT and creatinine are obtained before each treatment because of potential hepatic and renal toxicities.

Antitumor Antibiotics

These drugs act by DNA intercalation, interfering with topoisomerases and other mechanisms. They can exhibit cross-resistance with other drugs, mediated by the MDR drug efflux pump.

Doxorubicin

The most active single agent in treatment of lymphoma in dogs and highly effective in combinations for lymphoma in dogs and cats; broad-spectrum efficacy in treatment of solid tumors, particularly OSA, and in combinations with cyclophosphamide

Route: IV with caution for extravasation: slowly inject into the injection port on the line of a running infusion of 0.9% saline over 20 minutes; wait for the color to clear before giving next small amount.

NOTE: may be associated with histamine release and anaphylactoid reaction. Use plain normal saline for flushing—heparin may cause a precipitate to form.

Dosage: Large dogs: 30 mg/m²; small dogs: 1 mg/kg; cats: 1 mg/kg or 25 mg/m²; given every 2 to 3 weeks or according to protocol

Monitor: CBC, gastrointestinal signs (colitis, vomiting), liver function, electrocardiogram/echocardiogram; cats: monitor renal function

Mitoxantrone

Efficacious in combination with piroxicam for transitional cell carcinoma in dogs; moderate efficacy for lymphoma in dogs, low in cats; used as substitute for DOX in dogs at risk for cardiotoxicity and cats at risk for nephrotoxicity

Route: IV: slowly inject (with caution to prevent extravasation) into the injection port on the line of a running infusion of 0.9% saline over 10 minutes; wait for the color to clear before giving next small amount.

Dosage: Dogs: 5-6 mg/m² (5.5 mg/m² if less than 15 kg of body weight) every 3 weeks; cats: 5-6.5 mg/m² every 3 weeks

Monitor: CBC

Actinomycin-D

Alternative to DOX for canine lymphoma

Route: IV over 10 minutes with caution for extravasation: slowly inject into the injection port on the line of a running infusion of 0.9% saline over 10 minutes; wait for the color to clear before giving next small amount; discard unused solution.

Dosage: In protocol; 0.5 to 0.8 mg/m² IV every 1 to 3 weeks

Monitor: CBC and gastrointestinal signs

Platinum Drugs

Platinum compounds create cross-links in DNA. These drugs are similar to alkylating agents, and there is no cross-resistance with other classes of chemotherapeutic drugs.

Cisplatin

Efficacious in treatment of canine OSA and many carcinomas; not to be used in cats because of high risk of fatal pulmonary edema

Route: IV, intracavitary or intralesional, according to protocol

Dosage: *DO NOT USE IN CATS.*

Cisplatin *must* be preceded and followed by a diuresis period. Dogs (every 3-4 weeks):

<5 kg: 50 mg/m²; 5-20 kg: 60 mg/m²; >20 kg: 70 mg/m²

Administration: Needles or intravenous sets containing aluminum parts that may come in contact with solution should not be used for preparation or administration. Aluminum reacts with cisplatin, causing precipitate formation and loss of potency.

1. Pretreatment fluid diuresis: 4 hours at 18.3 ml/kg/hour using 0.9% NaCl
2. Antiemetic administration (e.g., dolasetron 0.6-1 mg/kg slowly IV) 15 minutes before cisplatin
3. Cisplatin: diluted in 6.1 ml/kg 0.9% NaCl to be given at same fluid rate over 20 minutes
4. Posttreatment diuresis: 2 hours at 18.3 ml/kg/hr using 0.9% NaCl

Monitor: Vomiting immediately after treatment (may need intravenous fluid support); CBC day 7 and 14 after treatment; renal function (serum creatinine and urine specific gravity) before each treatment

Cisplatin is excreted primarily in the urine over 48 hours following administration. *Avoid contact with urine and discard rather than wash soiled bedding.*

Carboplatin

Has efficacy similar to cisplatin without apparent renal toxicity; safe for use in cats

Route: IV, according to protocol; intracavitary or intralesional has been reported; 10 mg/ml diluted to a total dosage volume of 50 ml with 5% dextrose: slowly inject into the injection port in the line of a running infusion of 5% dextrose over 15-20 minutes

Dosage: Dogs (every 3-4 weeks): <15 kg: 250 mg/m²; >15 kg: 300 mg/m²; cats: 210 mg/m² for cats every 4 weeks (individual variability: see protocol)

In azotemic animals ideally calculate dose based on glomerular filtration rate if possible; otherwise arbitrarily reduce dose by 50% to 75%.

Monitoring: Creatinine before each treatment; reduce dose if creatinine is elevated; CBC at 7, 14, and 21 day

Enzymes

L-Asparaginase

Used in combination for lymphoma in dogs (not as single agent because of rapid resistance)

Route: SQ or IM (*can cause an anaphylactic reaction if given IV*)

Dosage: Dogs and cats: 10,000 units/m² (maximum dose at any one time is 10,000 units)

Reconstitute with 2 ml 0.9% NaCl slowly (will form bubbles if mixed too fast) to final concentration of 5000 units/ml.

Mitotic Inhibitors: Plant Alkaloids

Vinca alkaloids inhibit assembly of the mitotic spindle.

Vincristine

Curative for canine transmissible venereal tumor;
effective for lymphoma in dogs and cats; included in
some combinations for treatment of sarcomas; not
effective for mast cell tumor

Route: IV bolus with caution for extravasation

Dosage: 0.5-0.75 mg/m² or according to protocol

Monitor: CBC

Vinblastine

Effective for lymphoma in dogs and cats but less used
because of myelosuppression (making it harder than
vincristine to include with other drugs); efficacious
for mast cell tumors in dogs

Route: IV bolus with caution for extravasation

Dosage: 2 mg/m² every 7-14 days (but see individual
protocol)

Monitor: CBC 7 days after administration

Antimetabolites

Antimetabolites are analogs of normal metabolites and
are incorporated into DNA where they interfere with

enzyme activity or transcription or translation. These
drugs often have significant toxicity with low efficacy at
veterinary dosages; thus they are not in frequent use in vet-
erinary oncology.

CHAPTER 66

Anticancer Drugs: New Drugs

DOUGLAS H. THAMM, *Fort Collins, Colorado*

DAVID M. VAIL, *Madison, Wisconsin*

Of the treatment modalities available in veterinary
oncology, surgery remains the most commonly
applied and the most likely to effect cure. However,
local recurrence and/or distant metastasis result in the
majority of cancer-related deaths. The use of antineoplas-
tic chemotherapy has increased greatly in the last decade
in both general and specialty veterinary practice. Well-
designed clinical trials are constantly being performed to
determine the appropriate dose, tolerability, and efficacy of
novel antineoplastic drugs. General practitioners should be
aware of this expanding knowledge base, whether they will
be using these drugs in their practice or referring clientele to
centers elsewhere to receive them. There is ever-increasing
information regarding optimal doses, schedules, combina-
tions, and routes of delivery of “established” chemother-
apeutic agents in veterinary practice (see Chapter 65).
This chapter focuses on newer classical cytotoxic agents

(rather than “targeted” agents, monoclonal antibodies, or
antiangiogenic or immunomodulatory compounds) that
have U.S. Food and Drug Administration approval for use
in humans. A summary is provided in Table 66-1. For addi-
tional information, the reader is referred to other reviews
(Chun et al., 2004; Moore and Kitchell, 2003).

IFOSFAMIDE (IFEX)

Ifosfamide is an alkylating agent and has been evalu-
ated in tumor-bearing dogs and cats (Payne et al., 2003;
Rassnick et al., 2000; Rassnick et al., 2006a, 2006b).
It must be given during a diuresis and with a thiol
compound, sodium 2-mercaptoethane sulfonate (mesna),
to prevent sterile hemorrhagic cystitis induced by acro-
leins, a metabolite that is toxic to bladder urothelium.
Mesna and ifosfamide are sold and packaged together.

Table 66-1

Newer Cytotoxic Agents in Veterinary Oncology

Agent	Reported Dose	Documented Toxicity	Reported Efficacy
Docetaxel	<i>Dogs:</i> 20-30 mg/m ² slow IV infusion, q2-3 weeks (anecdotal); requires antihypersensitivity premedication <i>Cats:</i> Not established	Hypersensitivity (less severe than paclitaxel) Neutropenia likely to be dose limiting	Various carcinomas, some sarcomas (humans)
Gemcitabine	<i>Dogs:</i> 675 mg/m ² slow IV infusion q2 weeks <i>Cats:</i> Not established; anecdotally 250 mg/m ²	Neutropenia is dose limiting Gastrointestinal toxicity is generally mild and self-limiting Retinal detachment reported	Minimal activity reported; lymphoma, malignant melanoma, squamous cell carcinoma
Ifosfamide	<i>Dogs:</i> 375 mg/m ² slow IV infusion with mesna, q 2-3 weeks <i>Cats:</i> 900 mg/m ² slow IV infusion with mesna q3 weeks	Neutropenia is dose limiting Gastrointestinal toxicity is generally mild and self-limiting Urothelial toxicity avoided with concurrent use of mesna Nephrotoxicity reported in cats	Cutaneous hemangiosarcoma, leiomyosarcoma, vaccine-associated sarcoma
Paclitaxel	<i>Dogs:</i> 132 mg/m ² slow IV infusion q3 weeks; requires antihypersensitivity premedication <i>Cats:</i> Not established	Hypersensitivity Neutropenia is dose limiting Alopecia Gastrointestinal toxicity is generally mild and self-limiting	Osteosarcoma, various carcinomas, malignant histiocytosis
Pegylated liposomal doxorubicin	<i>Dogs:</i> 1 mg/kg IV q3 weeks <i>Cats:</i> 1 mg/kg IV q3 weeks	Cutaneous toxicity (PPES) is dose limiting in dogs—may be ameliorated by concurrent pyridoxine administration Nephrotoxicity is dose limiting in cats	Lymphoma, including doxorubicin-refractory cases; various sarcomas; various carcinomas; malignant histiocytosis; vaccine-associated sarcoma
Vinorelbine	<i>Dogs:</i> 15-18 mg/m ² IV weekly <i>Cats:</i> Not established	Neutropenia is dose limiting Gastrointestinal toxicity is uncommon	Pulmonary carcinoma, mast cell tumor (anecdotal)

IV, Intravenous; PPES, palmar-plantar erythrodysesthesia syndrome.

The recommended dose and delivery schedule in dogs is to give mesna (reconstituted in 0.9% NaCl to a concentration of 20 mg/ml) at 20% of the calculated ifosfamide dose. Mesna is first given as an intravenous bolus, and then the patient is diuresed with 0.9% NaCl at 18.3 ml/kg/hour for 30 minutes. Ifosfamide (375 mg/m² reconstituted in 0.9% NaCl to a volume of 9.15 ml/kg of body weight) is then given over 30 minutes, followed by an additional 5 hours of saline diuresis (18.3 ml/kg/hour). Two additional mesna doses are given at 2 and 5 hours during the postifosfamide diuresis. Ifosfamide can be dosed at either 2- or 3-week intervals in dogs. Phase I and subsequent phase II studies suggest that ifosfamide can safely be given at doses of 900 mg/m² every 3 weeks in cats using a similar administration protocol.

When given with mesna, the dose-limiting toxicity (DLT) of ifosfamide is myelosuppression, manifested primarily by neutropenia. Mild, self-limiting gastrointestinal toxicity (inappetence, vomiting, diarrhea) also can be seen. Nephrotoxicity has been reported infrequently in cats.

In one study of 72 tumor-bearing dogs, an overall response rate of 6% was reported. Responses were noted in dogs with sarcomas, including cutaneous hemangiosarcoma (HSA) and leiomyosarcoma (Rassnick et al., 2000). Only one of 40 dogs with lymphoma (LSA) responded. A protocol of alternating doxorubicin (DOX) and ifosfamide has been evaluated in dogs with HSA; when compared retrospectively to dogs treated with single-agent DOX, there

was no apparent improvement in outcome (Payne et al., 2003). Based on the published data, it is possible that the canine dose may be escalated further, which may improve antitumor activity. Ifosfamide appears to be an active drug for the treatment of feline vaccine-associated sarcoma (VAS); an overall response rate of 41% was reported in a recent phase II study (Rassnick et al., 2006b).

PEGYLATED LIPOSOMAL DOXORUBICIN (DOXIL, CAELYX)

Liposomes are closed vesicular structures that consist of one or more lipid bilayers. Several different types of liposome can be engineered with different physical properties that can dramatically alter drug pharmacokinetics and/or pharmacodynamics. Most liposomal formulations are designed to enhance antitumor efficacy, decrease normal tissue toxicity, or a combination of the two. Doxil, a liposomal formulation of DOX, has been used effectively in dogs and cats (Vail et al., 1997; Poirier et al., 2002). Unlike free (unencapsulated) DOX, myelosuppression and cardiotoxicity are not dose limiting. This makes it a suitable drug for use in dogs with preexisting cardiac disease or in dogs that have received cumulative doses of free DOX that are approaching cardiotoxic levels. The DLT in dogs is a cutaneous toxicity called palmar-plantar erythrodysesthesia syndrome (PPES), characterized by lesions ranging from mild erythema and alopecia to severe crusting and ulceration

primarily in the axilla, inguinal region, and skin surrounding the footpads. The severity of PPES can be diminished with concurrent use of vitamin B₆ (pyridoxine, 25 to 50 mg q8h orally [PO]) throughout treatment. The DLT of Doxil in cats is a delayed nephrotoxicity, although it is rare at the recommended dose; as with native DOX, adequate renal function is imperative in cats receiving the drug. The recommended dosage for Doxil in both dogs and cats is 1 mg/kg intravenously [IV] every 3 weeks as a 10-minute bolus.

Canine tumors reported to respond to Doxil include LSA, malignant histiocytosis, soft-tissue sarcomas, mammary adenocarcinoma, anal sac adenocarcinoma, and squamous cell carcinoma. In addition, dogs with LSA resistant to native DOX have responded to Doxil, implying some mechanism of abrogating drug resistance. Feline VASs have been reported to respond to Doxil; however, native DOX appears as effective as the more expensive liposomal formulation. Anecdotal responses have also been seen in cats with various carcinomas and cutaneous HSA.

PACLITAXEL (TAXOL; GENERICS ALSO EXIST)

Paclitaxel, originally extracted from the bark of the Pacific yew tree, is an inhibitor of microtubule depolymerization that results in mitotic arrest. It has significant activity in several types of human epithelial cancers and has recently been evaluated in veterinary practice (Poirier et al., 2004a). The recommended dosage in dogs is 132 mg/m² by slow intravenous infusion once every 3 weeks. The most difficult aspect of paclitaxel administration is a result of the carrier, Cremophor EL, which is used to solubilize the drug. Cremophor EL is highly allergenic in most species, including dogs and cats. In the dog treatment with antihistamines and corticosteroids is required both before and during paclitaxel delivery. A premedication and infusion protocol has been devised to prevent or minimize hypersensitivity reactions (Box 66-1).

Box 66-1

Paclitaxel Premedication and Administration Protocol in Dogs

Day before treatment: 30-60 minutes before treatment:	Prednisone 1 mg/kg PO Diphenhydramine 4 mg/kg IM Cimetidine 4 mg/kg IV Dexamethasone sodium phosphate 2 mg/kg IV
--	---

Paclitaxel delivery protocol:

- Suspend paclitaxel (132 mg/m²) in a 10× volume of 0.9% NaCl for injection.
- Start IV infusion at 30 ml/hour for 10 min.
- If no hypersensitivity reaction noted, increase infusion rate to 60 ml/hour for 10 min.
- If no hypersensitivity reaction noted, increase infusion rate to 90 ml/hour until complete.
- If hypersensitivity reaction is noted, premedication is repeated and infusion rate reduced as necessary.

IM, Intramuscularly; IV, intravenously; PO, orally.

Other than hypersensitivity-related side effects during infusion, the DLT in dogs is neutropenia. Hair loss, vomiting, and diarrhea (usually self-limiting) are also observed. Antitumor responses have been observed in dogs with metastatic osteosarcoma, mammary adenocarcinoma, and malignant histiocytosis. Stabilization of disease has been observed in dogs with various carcinomas. Further evaluations in larger patient populations are currently under way; and, although paclitaxel can be difficult to administer, a subset of patients will benefit from its use. In our experience paclitaxel is extremely difficult to administer to cats; the hypersensitivity reactions are usually too severe to allow delivery of a therapeutic dose. Formulations of paclitaxel that do not use Cremophor EL are under development.

DOCETAXEL (TAXOTERE)

A drug related to paclitaxel, docetaxel (Taxotere, Sanofi-Aventis) is currently being evaluated in veterinary patients. It has antitumor activity in a variety of human carcinomas and some sarcomas. In humans and in dogs treated to date the incidence of severe hypersensitivity reactions appears less than with paclitaxel because of the absence of the Cremophor EL emulsifier. Patients are premedicated using a protocol identical to that used for paclitaxel. Docetaxel is then administered IV as a 2-hour infusion. Preliminary information suggests that a dosage of 20 to 30 mg/m² every 2 to 3 weeks is usually well tolerated by dogs and that neutropenia is likely to be dose limiting. There is no information regarding the use of docetaxel in cats.

VINORELBINE (NAVELBINE; GENERICS ALSO AVAILABLE)

Vinorelbine is a semisynthetic molecule in the vinca alkaloid class of drugs. Its mechanism of action is similar to that of other members of the group in that they disrupt polymerization of microtubules, especially those comprising the mitotic spindle apparatus, ultimately inducing metaphase arrest in dividing cells. In a recent phase I study in dogs, vinorelbine was well tolerated and, although efficacy was not a primary end point, preliminary evidence of antitumor effect was observed (Poirier et al., 2004b). The maximum tolerated dose was found to be between 15 and 18 mg/m² once weekly. It is recommended that treatment in dogs be initiated at 15 mg/m²; if toxicity is acceptable, escalation to 18 mg/m² should be considered. Neutropenia was the DLT. Anorexia, vomiting, diarrhea and one case of a cutaneous rash were also observed; but these generally were self-limiting and did not require hospitalization. Although no phase II trials have yet been reported for vinorelbine in canine cancer, the phase I trial suggested activity in dogs with primary lung tumors, and there is anecdotal evidence of efficacy against canine mast cell tumors, including those that have failed prior therapy with the related vinca alkaloid vinblastine. At present no published information exists for vinorelbine use in cats.

GEMCITABINE (GEMZAR)

Gemcitabine is an antimetabolite nucleoside (pyrimidine) analog that has been used in veterinary medicine, both as a direct cytotoxic agent and as a radiation sensitizer (Kosarek et al., 2005; LeBlanc et al., 2004). As with other nucleoside analogs, the mechanism of action of gemcitabine is attributed to its incorporation into deoxyribonucleic acid (DNA) and ultimate inhibition of DNA replication. Several anecdotal dosing regimens have been suggested; a biweekly (every 2 weeks) dosage of 675 mg/m² as a 30-minute intravenous infusion appears to be well tolerated in dogs. The drug is diluted in 10 ml/kg of body weight of 0.9% NaCl immediately before delivery. A safe dose in cats has not been published; however, anecdotally 250 mg/m² has been used. It appears that the biologic effect of gemcitabine may be influenced heavily by its duration of infusion: longer infusion times may result in increased intracellular conversion of gemcitabine to its active metabolite, resulting in increased toxicity or a necessity for dose reduction.

Gemcitabine has not been evaluated extensively in veterinary patients, but very limited antitumor efficacy has been reported in tumor-bearing dogs to date. Responses have been observed in a small number of dogs with LSA, malignant melanoma, and squamous cell carcinoma. Short-term (2 to 5 months) disease stabilization was also observed for some other canine tumor types and a small number of cats with oral squamous cell carcinoma.

Hematologic and gastrointestinal toxicity in dogs at the suggested dose appears mild and self-limiting in most cases. One case of retinal detachment in a dog receiving gemcitabine has been reported. Twice weekly "radiosensitizing" doses of 50 mg/m² in the dog and 25 mg/m² in the cat were found to have unacceptable hematologic and local tissue toxicity in one study (LeBlanc et al., 2004).

Given their apparent synergy in human studies, combinations of gemcitabine and carboplatin currently are being evaluated in veterinary patients.

Radiotherapy: Basic Principles and Indications

ERIC M. GREEN, *Columbus, Ohio*

Radiotherapy (RT) is the treatment of disease using ionizing radiation. Just over a year after the discovery of x-rays by Wilhelm Konrad Röntgen in 1895, Wilhelm Alexander Freund, a German surgeon, reported the disappearance of a hairy mole in a human patient after treatment with x-rays. Years later in 1906 Richard Eberlein, a German physician and veterinarian, first reported the use of RT in animals. Today veterinary RT is a growing field with roughly 63 radiation oncologists worldwide certified by the American College of Veterinary Radiology. There are now 65 private veterinary practices and universities in the United States that offer RT as part of a comprehensive approach to cancer care listed on the Veterinary Cancer Society's website (www.vetcancersociety.org).

This chapter provides a basic understanding of the principles of RT, reviews the indications for RT, and discusses some of the common side effects of treatment.

PRINCIPLES OF RADIOTHERAPY

Radiation is classified as either particulate or electromagnetic. Particulate radiations are those that have mass and may have a charge and include electrons (also known as β -particles), protons, neutrons, and α -particles (a helium nucleus). Electromagnetic radiations are those that have no mass and no charge. These are merely packets of energy (photons) and include x-rays and γ -rays. These two differ only in their method of creation. X-rays are created through the interaction of fast-moving electrons with a heavy metal target as in an x-ray tube or linear accelerator, whereas γ -rays arise from the nucleus of radioactive elements. All of the listed particulate and electromagnetic radiations can be used for the purposes of RT. Most often photons from a linear accelerator are used for RT; thus from this point forward it will be assumed that irradiation will be performed using photons.

To be useful for therapeutic purposes, the radiation used must be energetic enough to ionize atoms within the patient. It is this ionization process that begins the cascade of cellular damage. Ionizing radiation is capable of causing cellular damage through either a direct or an indirect action of the radiation within tissue. One third of the time when a photon enters a patient, that photon strikes an electron within an atom, giving it enough energy to knock it out of its orbit (creating a positive ion—the remaining atom without its electron). This free electron then goes on to cause damage to the cellular deoxyribonucleic acid (DNA). This is termed *direct action*. The other two thirds of the time the free electron liberated by the

photon interaction interacts with water molecules near the DNA, creating free radicals, which damage the DNA. This is termed *indirect action*. Oxygen must be present at the time of irradiation for the effects of the indirect action to be most damaging. This is because oxygen binds to the DNA/free radical combination, fixing (making permanent) this free radical damage.

The resulting damage to the DNA is the same whether it is a result of direct or indirect action and is in the form of single- and double-strand breaks. Single-strand breaks occur with great frequency but are often of little consequence. Given enough time, cells can repair much of this type of damage. Double-strand breaks occur at the rate of 4 for every 100 single-strand breaks but are of greater significance. They are more difficult for the cell to repair and therefore often result in the death of the cell, by either initiating the apoptotic pathway or creating chromosomal aberrations that result in cell death at a subsequent mitosis. Since radiation kills cells, RT is potentially useful for the treatment of cancer. However, radiation does not discriminate between neoplastic cells and normal cells, and the death of the normal cells in the treatment field results in radiation side effects. This collateral injury is minimized by careful therapy planning.

Repair and Fractionation

As previously mentioned, both normal and tumor cells often can repair some of the DNA damage caused by ionizing radiation. Generally only the single-strand breaks can be repaired. To repair all the single-strand breaks, the cell must have enough time. It is generally believed that about 6 hours is required for normal tissues to repair most radiation-induced single-strand breaks. The repair that occurs in the normal tissues is advantageous since it allows these tissues to tolerate a subsequent dose of radiation without experiencing the same amount of cell death as the tumor tissues. The other advantage relates to the fact that tumors repair DNA inefficiently. This very important fact allows RT to be successful. If normal and neoplastic tissues had the same response to radiation, it would be impossible to treat tumors effectively without inducing significant, life-threatening side effects in the normal tissues. The goal of the radiation oncologist is to deliver enough radiation in a way that allows the normal tissues to best tolerate the damage while killing the tumor cells. This is achieved through *fractionation*, the delivery of multiple doses of radiation at intervals that

allow the normal tissues time to repair DNA damage. During the interval between radiation treatments, the tumor cells repair some of the single-strand breaks. At the next irradiation additional single-strand breaks are created that may be in close proximity to unrepaired breaks so that they effectively act as a double-strand break.

Each single dose of radiation kills the same percent of cells each time. Therefore it is unlikely that one large dose of radiation is sufficient to kill all the cells in a tumor. By fractionating the therapy, many smaller doses of radiation are delivered to the patient, killing a percentage of the remaining cells each time. If enough doses are delivered, the number of tumor cells remaining is very small, and the likelihood of recurrence is minimal.

Dose and Fractions

The term *dose* is used to refer to the amount of radiation absorbed by the patient. It is a measure of the amount of energy deposited in a known mass of tissue. The accepted International System of Units (SI) unit is the gray (Gy), which represents 1J of energy deposited in 1 kg of mass. Older literature may refer to radiation dose in units of the rad, where 100rad are equal to 1 Gy.

The term *fraction* is used to refer to an individual treatment of radiation. Radiotherapy protocols are designed to deliver a given total dose in a given number of fractions. Fractions are usually given daily (Monday through Friday) or once weekly, depending on the goal of therapy. Typical protocols may range from several weekly fractions of 8 to 10 Gy to daily fractions of 2.5 to 4.2 Gy for 2 to 4 weeks.

Sensitivity to Radiation

Both normal and tumor cells vary in their sensitivity to the effects of radiation. Some characteristics of cells increase sensitivity to radiation damage. In 1906 French radiobiologists Bergonié and Tribondeau stated,

“...X-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a longer dividing future ahead, on those cells the morphology and the function of which are least fixed...”

This means that sensitive cells are those that are mitotically active, undergo many divisions, and are undifferentiated. In general this would mean that most tumors and rapidly dividing normal tissue stem cells are the most radiosensitive. This is good in the sense that tumor cells die when irradiated and at the same time bad because the sensitive normal tissues suffer the same fate. One can rank normal tissues by their relative radiosensitivity in the following order from most sensitive to least sensitive: rapidly dividing stem cells (bone marrow, skin, mucosa, conjunctiva); intermediate stages in the hematopoietic series; connective tissue cells (endothelium); most parenchymal organs and glands; and granulocytes, myocytes, and neurons. It is the sensitive normal tissues in the radiation treatment field that need to be considered when planning RT because the death of these tissues leads to side effects.

INDICATIONS FOR RADIOTHERAPY

The decision to include RT in a patient's course of cancer therapy is based on several factors. RT can be used in several circumstances, depending on the desired outcome. Often the first choice that needs to be made is whether to offer definitive or palliative RT. Definitive therapy usually involves a protocol of several weeks of daily fractions and is intended to result in long-term tumor control. Typically one can expect some acute side effects with definitive protocols, but usually the risk of late side effects is low because of the smaller fraction sizes. Palliative therapy usually involves a protocol of once-weekly treatments for 3 to 4 weeks and is intended to result in the alleviation of pain or clinical signs and/or to achieve short-term tumor control. Acute side effects generally are not observed with palliative protocols since the goal is to improve the patient's quality of life with the treatment; but the risk of late side effects is far greater because of the large dose per fraction. One needs to weigh the risks of both acute and late side effects against the length of tumor control or improved quality of life that is expected with each protocol. In determining the appropriate treatment protocol for each patient, one can look at several factors: tumor type, tumor grade and stage, and tumor location.

Tumor Type

It is well established that different tumor types have different inherent radiosensitivities. Higher doses of radiation are required to control some types (sarcomas), whereas others may require a lower dose (carcinomas). Some tumors respond better to higher doses per fraction given weekly (melanoma), whereas most others require smaller doses per fraction delivered daily.

Tumor Grade and Stage

These are often prognostic, and it is important to understand the implications of each. The histologic grade may predict a more aggressive behavior that may require a more aggressive radiation protocol. The clinical stage may suggest that a definitive protocol may not be appropriate or that regional lymph nodes may need to be included in the same or separate treatment field. It may also be inappropriate to use a definitive protocol on a patient that has a poor long-term prognosis as predicted by the tumor grade and stage or serious concurrent illness.

Tumor Location

Because the normal tissues around the tumor experience side effects from the radiation, it is important to use a protocol that these tissues can tolerate without experiencing life-threatening damage. Most RT protocols are designed to treat to the tolerance of the normal tissues in the treatment field such that the acute side effects in those tissues are acceptable. Occasionally the protocol must be modified to account for larger treatment fields that may include large volumes of normal tissue.

The previous factors merely allow one to select the most appropriate RT protocol based solely on tumor-related

factors. One also needs to consider the owner's expectations, as well as whether the patient has concurrent disease or can tolerate the daily or weekly anesthesia required to undergo RT. Financial issues may also be of concern for owners; and, whereas a definitive RT protocol may be the treatment of choice, it is often expensive. A less expensive palliative protocol may be a reasonable option for owners who want to do what they can but do not have the financial means. In addition, the factors listed previously more often than not will demonstrate the need for a multimodality approach that may involve surgery and/or chemotherapy in conjunction with RT.

Combination Therapy: Surgery and Chemotherapy

Frequently more than one modality is necessary to affect the greatest tumor control in a patient. For many tumors surgery is used to remove the gross tumor, and RT used to treat the remaining microscopic disease. Systemic chemotherapy may also be used to address the potential for metastatic disease in the same patient; and in some circumstances, particularly when the tumor is very large, surgery may be used after RT. There are advantages and disadvantages to both preoperative and postoperative RT; these need to be considered on an individual patient basis.

The primary advantage of preoperative RT is that a smaller treatment field can be used, thus minimizing the normal tissue side effects. The gross tumor can be treated most effectively because its exact location is known, either by palpation or imaging. To account for microscopic extension, a margin of normal tissue around the gross tumor is included in the treatment field. The resulting radiation field is smaller before surgery because a postoperative field would need to include any surgical scar (always larger than the original tumor) and a margin around it. Radiotherapy has the potential to improve the resectability of tumors by shrinking them before surgery. In addition, because of the tumor cell death, the risk of metastatic spread at the time of surgery theoretically is reduced with preoperative RT. The major disadvantage of RT before surgery is the potential for surgical complications such as delayed wound healing. Theoretically the entire radiation field should be removed surgically, and the wound closed with unirradiated tissue opposing itself. Realistically this is unlikely to be the case; thus care must be taken to close the wound securely and avoid excessive tension. One other disadvantage is that surgery must wait until the acute side effects of the radiation have healed. During this time the tumor continues to grow and may have more opportunity to metastasize.

The primary advantage of postoperative RT relates to the concept that radiation is more effective at eradicating smaller number of cells left behind after surgery than large number of cells present in the gross tumor. Additional advantages include the immediate removal of the tumor and therefore a lower risk of metastasis. Furthermore, critical information may be gained at surgery that may influence further therapy (i.e., regional lymph node status or the presence of disease not detected by prior imaging studies). Disadvantages of postoperative RT include

the larger treatment field needed (increasing the normal tissue side effects) and the fact that the RT must wait until any surgical complications have healed (e.g., seroma, hematoma). Important also is the issue that without accurate original tumor information (size and location), the radiation oncologist must increase the field size because the surgical scar may not relate well to the original tumor site, particularly if the tumor was not in the skin. This is a particular problem for cases that are referred for RT to another hospital after surgery. To minimize this disadvantage, surgeons are encouraged to take photographs of the tumor before surgery and place hemoclips at all margins of the surgical bed. Radiographs or computed tomography images can then be obtained of the tumor site to aid in RT planning.

The decision to combine chemotherapy with radiation should be based on the metastatic potential of the tumor. Also, chemotherapy may act synergistically with the radiation to result in a greater tumor cell kill than either modality alone. However, care should be taken when combining chemotherapeutics that are known radiosensitizers since the acute side effects in the normal tissues are likely to be more severe. A true radiosensitizing chemotherapeutic could be used at a dose much lower than the conventional systemic dose to enhance the cell-killing effects of the radiation while avoiding normal tissue acute side effects. In that case the agent would not be as effective at controlling metastatic disease with the lower dose.

Very little is published in the veterinary literature describing appropriate radiosensitizing doses. It may be prudent to delay chemotherapy until after the RT protocol is complete when using radiosensitizing agents at systemic doses. A short list of agents known to be radiosensitizers includes: 5-fluorouracil, cisplatin, carboplatin, etoposide, gemcitabine, and paclitaxel. Another consideration when using chemotherapy after RT is radiation recall. This is the manifestation of acute side effects within the radiation field well after the conclusion of RT when certain chemotherapeutics are given. Although not yet reported in the veterinary literature, this is a well-established phenomenon in human patients subsequent to the administration of actinomycin, doxorubicin, methotrexate, 5-fluorouracil, hydroxyurea, and paclitaxel.

SPECIFIC TUMOR APPLICATIONS

Many veterinary tumors may benefit from treatment with radiation. What follows is not meant to be all-inclusive, but represents the most common applications for RT in veterinary medicine.

Brain Tumors

The exact histologic type of brain tumor in a dog or cat is rarely known, although inferences can be made from the imaging characteristics and epidemiologic data. Regardless, RT is the treatment of choice for inoperable or incompletely resected brain tumors. A recent review suggests survival times of 700 days in patients who received definitive RT (Bley et al., 2005). Stereotactic radiosurgery (a technique that pinpoints radiation in the

tumor and spares more normal brain tissue) holds great promise with a few reported survival times of 56, 66, and 227 weeks (Lester et al., 2001). This technique requires advanced equipment not readily available to all radiation oncologists.

Nasal Tumors

Radiotherapy is *essential* in the treatment of most nasal tumors and results in survival times of 12 to 19 months with definitive protocols. Palliative protocols have been described and result in a modest survival time of 7 months (Mellanby et al., 2002). Recently post-RT nasal exenteration has been described as an option for select patients with mid-to-rostral nasal cavity tumors and has resulted in an overall median survival time of 48 months (Adams et al., 2005).

Oral Tumors

Surgery is often the treatment of choice for most oral tumors; thus cosmetic and functional outcome following resection is an important consideration. Patients with small, rostrally located tumors fair far better after surgery because resection is often curative. In cases in which aggressive surgery may be associated with unacceptable morbidity, a less aggressive surgery followed by RT may prove most beneficial for the patient. This approach using a definitive RT protocol is reasonable for most carcinomas and sarcomas of the oral cavity. Acanthomatous epulides are a special case in which definitive RT alone often results in long-term durable tumor control. Oral melanomas present a different dilemma in that they are highly metastatic, but local control is often necessary for preservation of quality of life. A palliative protocol combined with platinum-based chemotherapy as a radiosensitizer resulted in a median survival time of 1 year (Freeman et al., 2003).

Soft-Tissue Sarcomas

As with oral tumors, surgery provides the greatest chance for tumor control, but many tumor locations prevent wide excisions (head or extremities). Again RT can control the residual microscopic disease left after incomplete excision. For many well-differentiated soft-tissue sarcomas (fibrosarcoma and peripheral nerve sheath tumor), tumor control rates at 1 and 2 years following surgery and definitive RT are 95% and 91%. Vaccine-associated sarcomas in cats require a more aggressive approach. Radiation, either before or after surgery, followed by chemotherapy provides the longest survival times, about 500 to 600 days.

Mast Cell Tumors

The different grades of mast cell tumors present a unique challenge when deciding how best to treat them. For tumors of any grade, complete surgical excision with wide margins should be attempted. When resection is incomplete, RT and chemotherapy provide options for follow-up treatment. The 3-year recurrence rate for moderately differentiated mast cell tumors treated with surgery and

RT is only 7% (Frimberger et al., 1997). When the regional lymph node is positive, RT of both the primary site and the lymph node combined with prednisone can result in good long-term control approximating 41 months (Chaffin and Thrall, 2002). Incompletely resected grade III mast cell tumors or other grades with visceral metastasis may still benefit from a palliative RT protocol combined with chemotherapy. Radiotherapy for multiple cutaneous mast cell tumors is often impractical.

SIDE EFFECTS OF RADIOTHERAPY

Normal cells in the treatment field die as a result of irradiation. This often results in clinical side effects. These side effects of RT can be divided into two categories based on when they occur. *Acute effects* occur during or shortly after RT in rapidly dividing normal tissues (epithelium, mucosa, conjunctiva) in the treatment field. They are the result of the death of the stem cell population in these tissues. Acute effects occur after a threshold dose is received and become more severe as the dose is increased beyond that threshold. They typically result in inflammation and ulceration of the tissues and specifically include oral mucositis and desquamation. They often begin within the final week of treatment. Because these tissues are rapidly dividing, they replenish themselves, provided all of the stem cells are not destroyed, and the acute effects resolve 2 to 3 weeks after therapy is complete.

Oral mucositis is often a consequence of irradiation of nasal or oral tumors. It usually begins as erythema and inflammation of the oral mucosa and may progress to ulceration with sloughing of the superficial layers of oral epithelium. Excessive salivation often accompanies the mucositis. The patients frequently become inappetent because of pain. The medical management of oral mucositis consists of antibiotics to combat secondary infection of the damaged mucosa and analgesics. Maintaining appropriate hydration and caloric intake is essential while the patient is experiencing mucositis. Owners are encouraged to feed soft food and provide plenty of fresh water for their pets while the mucositis heals over 2 to 3 weeks. Occasionally esophagostomy or gastrostomy tubes are placed as a temporary measure to allow adequate hydration and nutrition until mucositis subsides.

Desquamation results after irradiation of the skin exceeds a threshold dose. Like mucositis, desquamation begins as erythema but can progress to dry desquamation (flaking of epithelium) or even moist desquamation (loss of superficial epithelium and oozing of serum onto skin). Hair loss (temporary or permanent) and changes in skin or hair color may also occur but are usually only a cosmetic issue. Management of desquamation focuses on limiting self-trauma and keeping the area clean and dry. Topical creams or ointments generally are avoided, and there is little support in the literature for their use. Elizabethan collars are essential to prevent the patient from licking the site because this exacerbates the wound. Nonadherent light dressings may be used, but only to keep the area clean, and should be changed frequently to prevent the treatment area from staying too moist. Oral antibiotics may be used in patients with moist desquamation to prevent a secondary infection because the

epithelial barrier to bacterial invasion is destroyed. Oral analgesics often are necessary since desquamation can be quite uncomfortable.

The likelihood of experiencing acute effects is related to the total dose of radiation delivered and the total time of the entire treatment protocol. If one delivers a high dose of radiation in a short period of time, the acute effects are severe and cause significant morbidity. However, this situation is best for tumor cell kill and ultimately tumor control. Radiotherapy protocols must carefully balance an acceptable level of acute side effects with an acceptable duration of tumor control to be most effective and useful.

Late effects are those that occur several months after RT in slowly proliferating normal tissues (often endothelium or parenchymal cells) in the treatment field. The cells in these tissues eventually die when they undergo mitosis. Because there are no stem cells to replace these lost cells, late effects are permanent changes. Late effects can be a consequence of endothelial cell death that results in areas of ischemia and subsequent tissue fibrosis. Specific examples of late effects include bowel stricture, cataracts, demyelinating myelopathy, osteoradionecrosis, keratoconjunctivitis sicca, and skin fibrosis. Frequently little can be done once late effects manifest themselves clinically, and management of these side effects focuses on controlling the clinical signs that are associated with the late effect. Surgery may be required to correct a bowel stricture or repair an oronasal fistula secondary to osteoradionecrosis. Certainly some late effects can be catastrophic and may result in the euthanasia of the patient because of quality-of-life concerns. This situation is avoided as best as is possible by choosing an appropriate RT protocol.

The likelihood of experiencing late effects is related to the dose per fraction. The larger the dose per fraction, the more likely it is that late effects will occur. It is important to be aware of the expected life span after treatment with RT protocols that use large doses per fraction. Typically palliative protocols designed to relieve pain or gain short-term tumor control have large doses per fraction. These protocols are carefully reserved for patients that are not expected to live a very long time after therapy; thus the

potential risk of experiencing a late effect is minimized. With most definitive RT protocols, the risk of late effects is very low, which is important as long-term tumor control is expected.

Surgical Oncology Principles

JAMES P. FARESE, Gainesville, Florida

Animals with cancer often have very advanced (locally invasive or metastatic) disease. It is imperative that veterinarians consulting with owners have a strong knowledge base regarding the behavior of the tumors that commonly occur in dogs and cats. Insufficient knowledge may preclude the appropriate diagnostic testing and procedures commonly performed by oncologic specialists. Many tumors demand an aggressive surgical approach that can only be delivered effectively by an experienced operator. In these cases referral to a specialist should be considered because *the best chance to remove a tumor is the first attempt*. In addition to knowing when tumor resection is possible, it is equally important to realize when the extent of disease has become too advanced to recommend surgical treatment. Veterinarians must always be mindful of the impact of any intervention on the quality of their patients' lives. Convincing owners of the importance of quality of life can be a difficult task when owners struggle to accept the limitations of the therapies that are currently available.

TUMOR EXCISION

One fundamental of oncologic surgery is an understanding of the classification scheme that describes different types of tumor excision. This nomenclature, published by Enneking (1983), serves as an important means of communication between oncologists.

Intracapsular

The intracapsular approach involves piecemeal removal of a mass with the dissection plane interior to the tumor capsule. It is a debulking or cytoreductive surgery that leaves behind macroscopic disease, making local recurrence almost guaranteed if the tumor is malignant. This approach is commonly used to treat benign diseases such as bone cysts, select malignancies (such as invasive thymoma reduction to alleviate clinical signs) or to improve the probability of radiation therapy controlling local disease.

Marginal

A marginal excision is immediately outside the tumor pseudocapsule with the dissection plane through the reactive zone (a layer of reactive tissue consisting of proliferating mesenchymal cells, inflammatory cells, and neovascularization). This technique generally is used for benign tumors (e.g., lipoma); when used for malignant

tumors, it often results in residual microscopic disease. When used for malignancies, this approach is often combined with adjunctive radiation therapy (RT). For example, a low-grade soft-tissue sarcoma (STS) of the extremity could be removed with a marginal excision followed by postoperative RT to address the potential for local recurrence if the margins are incomplete.

Wide

A wide excision is removal of the mass; pseudocapsule; reactive zone; and a wide margin of normal tissue (e.g., 2 to 3 cm) or an anatomic mesodermal barrier to tumor cell migration such as fascia, cartilage, or bone. Because the entire tissue compartment (e.g., entire bone or muscle belly) is not removed, it is possible that "skip" metastases (satellite tumor colonies nearby but separate from the primary mass) could be left behind. There is some controversy regarding the necessary margin width for curative surgery. However, most surgeons accept the 3-cm rule in all directions for tumors such as mast cell tumors (MCTs) and STSs. It has also been suggested that 2-cm margins may be satisfactory for grades I and II MCTs (Simpson et al., 2004). Tumor identity and grade impact margin width. For example, low-grade STSs may require smaller margins, whereas other tumors such as vaccine-associated sarcomas call for maximal margin width because of the fingerlike extensions along fascial planes.

Radical

A radical excision is an en bloc removal (removal of the primary mass, draining lymphatic vessels, and lymph nodes [LNs] with a single incision) of a mass and the entire tissue compartment that contains it. The dissection plane is extracompartmental (the compartment refers to the tissue planes that act as natural barriers to tumor invasion). This technique is often used during limb amputations for appendicular osteosarcoma and radical mastectomy for mammary neoplasia.

UNDERSTANDING TUMOR BIOLOGY

All tumors are not created equal, and even within the benign and malignant categories there is wide variation in tumor behavior. It is critical that the surgeon be familiar with the individual tumor types since tumor identity impacts many aspects of case management. In general carcinomas metastasize via the lymphatic system, and

sarcomas via the hematogenous route. However, the two vascular systems are connected by lymphovenous communications, and there are exceptions to these patterns. A strong knowledge base enables the surgeon to perform thorough physical examinations and educate the client about tumor behavior (i.e., degree of local invasion, patterns of metastasis), important staging tests, the type of resection required for cure, and long-term prognosis. Perhaps the best example of the importance of understanding tumor behavior is illustrated by the behavior of appendicular osteosarcoma. In these cases it is critical that the client understands that, despite “clean” chest radiographs, dormant micrometastasis in the lungs likely is present and that the possibility of cure is extremely low. Knowing tumor behavior helps guide these preoperative staging evaluations.

CLIENT COMMUNICATION

It is essential that the surgeon develop a good relationship with the client and communicate effectively. Owners of pets with cancer are often anxious and overwhelmed about the condition of their pet, making effective communication challenging. Given the aggressive nature of some surgical resections (e.g., nasal planum resection), it is important that the surgeon prepare clients for the expected postoperative appearance of their pet. This is best done by creating a library of images and videos depicting immediate postoperative and follow-up appearance from other cases. It is imperative that the client have a good understanding about the patterns of the disease, the likelihood of local recurrence, and the overall prognosis.

Almost as important as knowing when to recommend surgery is knowing when the disease state is too advanced to warrant surgery or will cause the patient to have a poor quality of life because of the extent of the resection. For example, resection of a large thyroid carcinoma that is fixed and invading underlying tissues would likely be incomplete and associated with significant hemorrhage and high morbidity. Furthermore, this surgery would not likely be curative because of local tumor thrombi and/or metastatic disease. The value of this determination cannot be overemphasized, and the ability to communicate this effectively to clients takes experience. Reactions from clients vary greatly as to what they view as acceptable surgical procedures. Some clients may be comfortable with radical laryngectomy and a permanent tracheostomy for a laryngeal neoplasm; others will not consider limb amputation because they cannot bear the thought of seeing their pet with such an altered appearance. Clients who initially are reluctant to have a certain procedure performed often change their minds once they have had a chance to reconsider the information and encouragement provided by the surgeon. At the same time, the surgeon must not impose a decision on clients who are undecided about surgery and must ensure the client is comfortable with the plan. Many veterinary cancer centers use mental health professionals to assist with the surgeon-client communication and provide support to clients during the decision making and/or treatment process.

TUMOR STAGING

In the approach to case management there are two important considerations: (1) whether to obtain a preoperative biopsy, and (2) the extent of preoperative staging. These questions are usually easy to answer in hindsight. Staging varies, depending on tumor type, but typically consists of thoracic radiographs and aspiration of regional LNs, with or without abdominal imaging. It is important to understand that a lack of LN enlargement does not mean that nodal metastasis has not occurred.

The value of knowing the tumor identity before surgical excision cannot be disputed since tumor behavior can influence case management in many ways: degree of local invasion, metastatic potential, and biologic activity (e.g., release of histamine, heparin with manipulation of an MCT). However, the decision of whether to obtain a preoperative (versus postoperative) biopsy is not always straightforward. A major consideration is whether the information obtained will affect case management. A good example of this is the handling of oral tumors. The types of oral tumors vary widely in their behavior. For example, the treatment of a fibromatous epulis differs drastically from that of a fibrosarcoma. Aside from melanomas, many oral tumors have a similar gross appearance. Thus it is essential in this scenario that veterinarians perform preoperative biopsy and properly stage the disease if they are to educate the client and help them make an informed decision.

Regarding biopsy techniques for tumor diagnosis, consideration also should be given to the invasiveness of the procedure and the potential for causing hemorrhage into a body cavity (e.g., a large, cavitated splenic mass) or the seeding of tumor cells into a body cavity or along a needle tract (e.g., a transitional cell carcinoma of the urinary bladder). If the need for surgery is clear, as with a staged-clean cavitated splenic mass that is hemorrhaging, it may be in the patient's best interest to forego additional diagnostic efforts. The surgeon must decide whether the risks of the diagnostic tests are justified.

Incisional versus Excisional Biopsy

Incisional biopsy is the removal of a portion of a tumor by sharp incision. This technique is usually performed in cases in which knowing the specific behavior of a tumor may affect an owner's willingness to treat the pet surgically or when knowing the identity of the tumor would alter the treatment plan. Common methods include the following:

Wedge incision: Small, wedge-shaped section of tumor tissue removed with a scalpel blade or biopsy punch. For deeper subcutaneous tumors or those under superficial muscle bellies, a short skin incision is necessary to approach the mass.

Needle core biopsies: Large-bore needles used to sample deeper tumors or tumors of bone (e.g., Tru-cut for soft tissue, Jamshidi needle for bone). This type of tissue sampling can usually be performed with sedation and local anesthesia.

Disadvantages of the incisional biopsy approach are that it often requires a second surgical procedure to be

performed and it creates a direct communication between the tumor tissue and the surrounding normal tissue, possibly increasing the chance of local recurrence. The approach for incisional biopsy must be planned such that the incision site and entire dissection tract can be easily excised during the definitive resection. For example, for a mandibular oral tumor the biopsy should be performed through the overlying oral mucosa rather than through skin that is intended to be preserved.

In contrast, excisional biopsy is the removal of the entire tumor (usually a small mass) with a surrounding barrier of normal tissue. The main advantage is that biopsy and gross tumor removal are performed in a single procedure. The main disadvantage is that, if the tumor is highly invasive and the surgeon does not know the identity of the tumor, he or she may not plan a wide enough resection to completely remove the tumor. Cytology results and the anatomic location are important factors in deciding which approach to use. For example, cytology results may be diagnostic for an MCT, obviating the need for a tissue biopsy. Tumors in the flank region may allow an excisional biopsy to be performed with wide (i.e., 3-cm) margins, whereas the same approach on a distal extremity would result in a large open wound that would not allow primary closure. Other instances in which excisional biopsy is almost exclusively performed include intrathoracic and intraabdominal masses, since the invasiveness of the biopsy procedure may involve too much risk or equal the morbidity of the definitive resection if an open biopsy is performed.

When performing an incisional or excisional biopsy on a tumor of unknown histotype, it is important to forewarn the owner that the main purpose of the biopsy is to *establish a diagnosis*; additional diagnostic tests, additional surgery, or other forms of therapy may be necessary following receipt of the histopathology results.

ROLE OF REGIONAL LYMPH NODES

Palpation (or ultrasonographic evaluation in deeper locations such as the sublumbar area) of regional LNs should become a reflex for clinicians evaluating tumors; and whenever needle aspirates can be safely performed, cytology should be done. There is still some controversy as to the role of the LN in tumor biology. The older Halstedian theory stated that tumor cells disseminate in an orderly anatomic manner of ever-larger circles (e.g., from the primary tumor to the closest draining LN and so on). An alternative theory is that cancer cells do not spread in an orderly manner and that regional LNs are largely ineffective barriers to cancer spread. Experimentally tumor cells have been shown to pass through LNs and appear in the efferent lymph within hours. Regardless of the role of the LN, there is some value in removal of LNs along with excision of the primary tumor. First, staging of the tumor can be performed if it was not possible via cytology before surgery. The other advantage to LN removal is that of cytoreduction since the tumor burden may be reduced to a microscopic level, making adjunctive chemotherapy and RT more effective. On the other hand, if preoperative LN cytology shows the node to be negative for metastatic cells, the LN should probably be left in place.

It has not been shown definitively that histopathology is superior to cytology for staging, and some important local immune function may be lost with removal of a normal LN.

PALLIATIVE SURGERY

When surgery is performed in an effort to make a patient more comfortable or improve quality of life and the surgeon knows that the procedure will not cure the patient of the disease, the treatment is considered palliative in intent. A good example of palliative surgery is limb amputation for canine osteosarcoma; although pulmonary metastasis has almost invariably occurred by the time of diagnosis, surgery can alleviate the pain associated with the primary bone tumor and dramatically improve the quality of life that remains.

CURATIVE-INTENT RESECTION

A thorough knowledge of anatomy is necessary when palpating the extent of a primary tumor and planning the resection. Aside from tumor size, factors that influence resectability include proximity to nonexpendable anatomic structures, degree of local tissue invasion, and tumor grade. Advanced imaging modalities such as computed tomography and magnetic resonance imaging provide a great deal of preoperative information; however, there are still instances in which it is not clear whether a given tumor is excisable until it is approached surgically. The final preoperative physical evaluation typically is done just after induction of anesthesia. In planning the resection it is essential that the surgeon appreciate the limits of various resection procedures. Consideration must be given to surrounding normal anatomic structures that can be sacrificed to achieve a complete excision yet not cause unacceptable postoperative morbidity or complications. For most cutaneous malignancies the general rule is to make a plan that will allow the surgeon to excise all tissue necessary for complete removal and consider wound closure secondarily. If an aggressive, curative-intent resection is performed and the wound cannot be closed routinely, the defect may be closed with a reconstructive surgical technique such as a skin flap or graft. Alternatively the wound can be left to heal by second intention. Skin flaps should be used with some caution because they usually increase the size of the surgical field and thereby complicate postoperative RT planning.

In some cases it may be prudent to plan a more conservative resection and accept that the surgical plan may result in microscopic residual disease. For example, a low-grade subcutaneous STS of moderate size on the extremity in a 14-year-old dog that is owned by a client who is opposed to the thought of postoperative wound management could be removed via a marginal excision. Although this approach alone would not likely result in a cure, the owner may prefer the possibility of local recurrence over a protracted course of wound management or limb amputation. However, this surgical approach should be questioned if the same patient is entirely asymptomatic and the tumor is slow growing.

There are several technical aspects to consider when performing tumor resections.

1. Perioperative antibiotics should be considered, and strict aseptic technique adhered to since some cancer patients can be immunosuppressed.
2. An open incisional biopsy creates a communication between the tumor tissue and the edges of the normal tissues in the dissection path. Thus excision of the biopsy tract is indicated to ensure removal of all tumor cells. Adequate excision of the biopsy tract is facilitated by well-planned biopsy approaches. Biopsy incisions should be oriented in a direction that is *parallel to the tension lines* to facilitate closure of the surgical wound following definitive resection of the mass and associated biopsy tract.
3. In some procedures such as nephrectomy for a renal neoplasm or lung lobectomy, it has been advocated to ligate the venous side first to minimize embolization of tumor cells into the venous circulation that may occur as a result of tumor manipulation.
4. Manipulation and handling of the tumor should be minimized. In addition to possibly causing more cells to gain access to systemic circulation, rupture of the tumor capsule might occur and allow tumor cells to seed the surgical field. Moistened laparotomy sponges wrapped around large tumors (such as a splenic mass) can be used to minimize the possibility of tumor rupture and glove contamination during the procedure. Excessive manipulation of MCTs can cause degranulation of mast cells and profound hypotension. For this reason patients with MCTs are often pretreated with diphenhydramine prior to surgery.
5. Once the tumor has been excised and removed from the surgical field, gloves and instruments should be changed, and a new pack of surgical towels should be placed over the original surgical drape to help prevent seeding of the wound. The wound should also be lavaged to wash away exfoliated tumor cells. Consideration should be given to the order of procedures if more than one mass resection or some other unrelated procedure (such as on ovariectomy) is planned during the same anesthetic episode. For example, it would be best to remove a subcutaneous lipoma before performing a cystotomy to excise a transitional cell carcinoma because of fear of seeding the incision with tumor cells.

HISTOPATHOLOGY

All excised tumors should be evaluated histologically. When submitting the specimen, the surgeon should provide the pathologist with a concise but accurate history and help the pathologist maintain proper orientation of the tissue. This orientation may be communicated by making a drawing and placement of a suture on a specified margin of the specimen. Knowing the orientation can be very helpful if tumor cells are observed extending to one of the tissue margins and further local therapy is indicated. Alternatively small tumor bed samples (i.e.,

small incisional biopsies of the wound bed following resection) can be harvested from areas of higher concern just before closure. Following removal of the mass the surgical margins of the excised specimen should be marked with ink to document the original plane of dissection. Inking the margins can be very valuable, particularly when it is necessary to reevaluate the submitted specimen after the initial sectioning has been performed. The ink is “painted” on with cotton-tipped applicators by the surgeon and should be allowed to dry for 5 to 10 minutes before the specimen is placed in formalin. Multiple colors are available; however, some pathologists prefer black or yellow since these colors cannot be confused with the hematoxylin and eosin tissue stains (blue and red). Like suture tags, different ink colors can be used to direct the pathologist to areas of greater concern. The volume ratio of formalin to tumor mass should be 10:1 to ensure proper fixing of tissue. With large tumors fixative incisions should be made 1 cm apart throughout the tumor parenchyma (similar to slicing bread) to allow proper fixation. However, it is critical that the surgeon not allow fixative incisions to connect to the surgical margins since that will lead to confusion when the pathologist examines the tissue.

INCOMPLETE RESECTION AND LOCAL RECURRENCE

Local recurrence often can be predicted with a good histologic assessment of the surgical margins. When “dirty margins” are not treated, a mass may appear along or beneath the line of incision weeks to months after the initial surgery, depending on the tumor histotype. In this scenario location, tumor histotype, and the results of restaging dictate the course of action. For example, a local recurrence of a synovial cell sarcoma of the tarsal joint previously excised in an aggressive manner is best treated by limb amputation provided there is no evidence of LN or pulmonary metastasis. In other cases additional surgery on the same operative site might be possible to remove the remaining neoplastic cells. In general, this approach is more likely to be effective soon after the initial surgery (i.e., when cells are still present at microscopic levels). Failing to include a fascial plane in the resection is one of the most common reasons for incomplete excision of subcutaneous masses. Although it is best to advise the client against taking the “wait-and-see” approach when incomplete margins have been documented histologically, a small percentage of these cases may never develop local recurrence.

ADJUNCTIVE RADIATION THERAPY

Alternative therapies such as RT and chemotherapy should also be considered in cases with incomplete excision, especially if an aggressive attempt at surgery was made during the initial procedure by an experienced surgeon and there is insufficient tissue to allow reexcision. Although adjunctive chemotherapy is rarely effective in “cleaning up” dirty margins after surgery, adjunctive RT can be a very useful tool for this purpose. For example, postoperative RT is often successful in treating incompletely

resected MCTs and STSs of the extremity treated by marginal excision. In some instances RT is more advantageous before surgery. The advantages and disadvantages of the two approaches follow:

Preoperative Radiation Therapy

The advantages of preoperative RT are that a smaller field is required, there is less tumor hypoxia (hypoxic cells are more resistant to radiation), and the extent of the surgical procedure potentially is reduced if the mass decreases in size. Although surgeons prefer not to operate through irradiated tissues, in some instances this approach may have its advantages (e.g., for feline vaccine-associated sarcomas because of their fingerlike extensions along fascial planes). The main disadvantage of this approach is that irradiated skin is more likely to develop incisional complications, especially if there is tension on the closure. Anecdotally some oncologists believe that feline skin is less sensitive to the effects of radiation than canine skin.

Postoperative Radiation Therapy

The advantages of postoperative RT are that there is no delay in surgery and there are no adverse effects on wound healing (if the incision is already healed at the time RT is

initiated). The main disadvantages are that a larger radiation treatment field is required and that hypoxia from microvessel surgical trauma may lower sensitivity of remaining tumor cells to radiation. When the surgeon is anticipating the need for postoperative RT, the incision should be oriented in a manner that optimizes the radiation treatment field. In addition, to facilitate radiation planning, metal hemoclips can be placed within the wound just before closure to mark the cranial, caudal, dorsal, and ventral extents of the surgical field (see Chapter 67 for more information).

CHAPTER 69

Canine Soft-Tissue Sarcomas

TANIA A. BANKS, *Albany Creek, Queensland, Australia*
JULIUS M. LIPTAK, *Guelph, Ontario, Canada*

TERMINOLOGY

Sarcoma is a broad term for a malignant tumor of mesenchymal origin. Soft-tissue sarcomas (STSs) are a particular subgroup of sarcoma. Specific histotypes falling under the STS classification include malignant peripheral nerve sheath tumor, hemangiopericytoma, malignant schwannoma, neurofibrosarcoma, fibrosarcoma, undifferentiated sarcoma, liposarcoma, leiomyosarcoma, myxosarcoma, myxofibrosarcoma, and rhabdomyosarcoma. They are grouped together because they possess similar biologic behavior and histologic features. The behaviors common to all STSs are:

- An ability to arise from any anatomic site in the body, although skin and subcutaneous tissues are most common.
- A tendency to appear as pseudoencapsulated soft-to-firm tumors.
- Exceptional local invasion of tissues and poorly defined histologic margins, with tumor cells infiltrating through and along fascial planes.
- A known potential for local recurrence after conservative or incomplete surgical resection (and recurrent tumors are notoriously more difficult to treat).

- A low-to-moderate metastatic rate.
- A tendency to metastasize hematogenously (e.g., to lungs).
- Regional lymph node metastasis unusual (except for synovial cell sarcomas and histiocytic sarcomas).
- A similar histologic appearance.
- Histologic grade predictive of metastasis and surgical margins predictive of local tumor recurrence.
- Measurable or bulky tumors (>5 cm in diameter) generally have a poor response to chemotherapy and radiation therapy (RT).

Some sarcomas are not included in the traditional STS classification because of more aggressive biologic behavior (e.g., higher metastatic rates) and different histologic features. These include osteosarcoma, chondrosarcoma, histiocytic sarcoma, hemangiosarcoma (HSA), synovial cell sarcoma, mesothelioma, lymphangiosarcoma, oral sarcoma, and malignant peripheral nerve root tumors.

INCIDENCE AND RISK FACTORS

STSs account for 15% and 7% of all skin and subcutaneous tissues in the dog and cat, respectively. The annual incidence of STSs is 35 per 100,000 dogs and 17 per 100,000 cats. The etiology is generally unknown; however, in dogs sarcomas occasionally have been associated with RT, trauma, foreign bodies, orthopedic implants, and the parasite *Spirocerca lupi*. In cats sarcomas have been associated with feline sarcoma virus, vaccines and other subcutaneous injections, and trauma (e.g., intraocular sarcoma). This discussion is limited to spontaneous, nonvaccine-associated STSs in dogs and cats (see Chapter 71 for feline vaccine-associated sarcomas).

CLINICAL FEATURES

Most STSs are solitary and occur in middle-aged-to-older dogs and cats. They are more common in medium- to large-breed dogs but can occur in any age or breed. STS often presents as a soft to firm, spherical, nonpainful cutaneous or subcutaneous mass over the trunk or extremities and can be fixed to the underlying tissue. They can originate in visceral or nonvisceral sites. Generally they are slow growing, and clinical signs are related to the site of involvement and degree of invasion.

DIAGNOSIS AND CLINICAL WORKUP

A complete physical examination of the animal is the first diagnostic step. The mass is palpated to give an idea of site, size, fixation to underlying or adjacent structures, and an initial assessment of the extent of local disease. The regional lymph nodes also should be palpated for enlargement and fixation to underlying tissues.

Fine-needle aspirates are recommended to exclude other differential diagnoses but are often insufficient for obtaining a definitive diagnosis of STS. In one study in which fine-needle aspirates were performed on STSs from 40 dogs, 15% were incorrectly diagnosed, a further 23% were nondiagnostic, and only 62% were correctly diagnosed (Baker-Gabb et al., 2003).

A definitive preoperative diagnosis of STS requires a needle core, punch, incisional, or excisional biopsy. The biopsy should be planned so that the biopsy tract can be included in the curative-intent treatment, whether it be surgery and/or RT, without increasing the surgical dose or size of the RT field. Excisional biopsies are not recommended since they are rarely curative and subsequent surgery required to achieve complete histologic margins is often more aggressive than surgery following core or incisional biopsies, resulting in additional morbidity and expense. Furthermore, multiple attempts at resection, including excisional biopsy, before definitive therapy have a negative impact on survival time in dogs with STSs.

Histopathologic grading (low, intermediate, high or I, II, III) is ascertained from large biopsy specimens and should always be requested from the pathologist. Tumor grade is predictive of behavior and prognosis and is critical to treatment planning. Less than 10% of grade I, 20% of grade II, and 50% of grade III STSs will undergo eventual metastasis. Higher-grade lesions also tend to grow more rapidly and are more locally invasive.

The tests performed for workup and clinical staging depend on the type and location of the STS but usually include routine hematologic and serum biochemical blood tests, urinalysis, three-view thoracic radiographs, and regional tumor imaging. Blood tests are usually within the normal reference range for most dogs with STSs; however, anemia and thrombocytopenia are relatively common in dogs with disseminated histiocytic sarcoma and HSA. Paraneoplastic hypoglycemia is reported with intraabdominal leiomyosarcomas or leiomyomas.

Further imaging of the local tumor may be required for planning the surgical approach or RT if the mass is very large, within a body cavity, fixed to underlying bone, or impinging on or in close proximity to vital structures. Three-dimensional imaging techniques such as computed tomography and magnetic resonance imaging are particularly useful for staging local disease. The surgeon may then better assess the feasibility of and more accurately plan an aggressive surgical resection. Other imaging modalities for staging the local tumor include survey radiographs, ultrasonography, angiography, and nuclear scintigraphy.

The most important diagnostic test for staging of metastatic disease is three-view thoracic radiographs since the lungs are the most common metastatic site for STS. Lymph node metastasis is uncommon with typical STS. Fine-needle aspiration or biopsy of regional lymph nodes should be performed in dogs with clinically abnormal lymph nodes or atypical STS with a high rate of metastasis to regional lymph nodes such as HSA, histiocytic sarcoma, lymphangiosarcoma, synovial cell sarcoma, leiomyosarcoma, and possibly rhabdomyosarcoma. Abdominal imaging (e.g., ultrasonography or advanced imaging) may also be used to assist in further staging in selected cases.

TREATMENT OPTIONS

Local tumor control is the most important consideration for optimal management of nonmetastatic STSs because of their locally aggressive behavior. On gross examination

STSs appear to be well encapsulated. This is not the case because microscopically the pseudocapsule is composed of compressed tumor cells. These peripheral cells are more aggressive and responsible for the invasion into adjacent normal tissues. “Shelling out” the tumor leaves behind the more aggressive subpopulation of these peripheral, invasive cells. Consequently recurrent lesions are often behaviorally more aggressive or of a higher grade than the initial lesion and may compromise the optimal treatment and long-term outcome for the animal.

Incomplete surgical excision for canine STS has been reported to result in a 60% probability of local recurrence within the first 12 months (Bostock and Dye, 1980), increasing in subsequent years. In one study 28% of dogs with incomplete surgical margins had local recurrence and were over 10 times more likely to have local recurrence than dogs with completely excised STSs (Kuntz et al., 1997).

Surgical Resection With Wide Margins

Surgical resection with wide margins provides the best chance for a cure for cats and dogs with STS. Proper preoperative staging and diagnosis provides essential information to formulate a surgical plan. Excision of the STS, with associated biopsy tracts and any areas of fixation (e.g., bone, fascia), with wide margins is the recommended treatment. The minimum recommended surgical margins are 3 cm of grossly normal tissue lateral to the tumor and one uninvolved fascial layer deep to the tumor.

In two different studies surgical resection with wide, histologically complete margins resulted in 90% to 100% local disease control and a 90% to 93% 1-year disease-free survival. In these studies resected specimens were processed and fixed to emulate their in situ dimensions as closely as possible, and surgical margins were evaluated using a standardized protocol. Resected specimens were pinned to cardboard to prevent shrinkage during fixation and processing, painted with tissue-marking ink to mark the entire surgical margin, and fixed in formalin for 24 hours. The deep margin was always the closest margin in cases of clean resection, or the dirty margin in cases of incomplete resection and therefore more likely to be a site of treatment failure than either lateral margin. In all but one dog, tumors resected with deep margins greater than 1 mm did not develop local recurrence because all had a layer of fascia resected as part of the deep margin. These studies showed margins of 11 to 30 mm may be acceptable for grades I and II STSs, especially when a deep uninvolved fascial layer is removed en bloc with the lesion. Another study reported that canine STSs removed with attempted wide margins, regardless of completeness of excision, had an 85% rate of local tumor control with a median time to recurrence of 368 days. In another study 79% of canine STSs resected with wide, complete histologic margins were controlled for 2 years. The extent of surgery was the only factor significantly associated with survival time in a series of 56 dogs with liposarcomas. Resection of liposarcomas with wide margins resulted in a median survival time of 1188 days, compared to 649 days for marginal excision and 183 days for incisional biopsy (see Chapter 68 for additional information regarding surgical oncology principles).

Marginal Resection and Adjuvant Radiation Therapy

If the tumor or previous scar cannot be excised with wide margins, particularly for STS of the extremity, marginal resection followed by adjuvant RT is recommended to prolong disease-free interval and preserve limb function. This treatment regimen ideally involves a radiation oncologist from the outset rather than use of RT as a rescue procedure. In two studies marginal resection followed with alternate-day megavoltage RT resulted in 16% local recurrence rate with a median time to recurrence of 700 to more than 798 days (Forrest et al., 2003; McKnight et al., 2000). The optimal fractionation scheme and total radiation doses for canine STS have not been determined; but cumulative dosages greater than 50 Gy are recommended, and local tumor control is better with higher cumulative doses. In some cases RT can be used before surgery to decrease tumor volume so that the tumor is more amenable to wide surgical excision. Ideally the use of RT should involve a team approach with the surgical oncologist and the radiation oncologist. (See Chapter 67 for additional information about radiation therapy.)

Radiation Therapy Alone

RT alone achieves local control in 48% to 67% of tumors in the first 12 months, with higher cumulative radiation doses resulting in better control rates; however, this reduces to 20% to 33% at 2 years. Thus RT is not considered adequate as sole therapy but is generally considered palliative. Hyperthermia alone (100% recurrence rate) or with adjunctive RT (65% to 91% response rate with a 1-year recurrence rate of 30% to 64%) has also been used for treatment of canine STS.

Chemotherapy

Candidates for chemotherapy include animals with distant metastasis, inoperable tumors (because of size or location), recurrent tumors not amenable to further surgical treatment or RT, and grade III STS. However, chemotherapy has a limited role (if any) in the management of canine and feline STS in any of these situations, based on the failure of any study to date to document a positive effect.

Three chemotherapy drugs are active in adult human STS: anthracyclines (doxorubicin [DOX] and epirubicin), ifosfamide, and dacarbazine. In dogs DOX is considered the most active single agent to treat STS with objective response rates of up to 23%. Mitoxantrone has a variable effect in canine STS with a 0% to 33% response rate; a response rate of 21% has been reported in cats, with better response rates in lower-grade tumors. Ifosfamide conferred a complete response rate of 15% in 13 dogs with sarcomas of skin, bladder, and spleen. However, in dogs the combination of DOX with either ifosfamide or cyclophosphamide does not appear to be more efficacious than DOX alone. Antitumor responses observed following chemotherapy are usually incomplete and of short duration. The response of humans with extremity STS to preoperative DOX was prognostic in one study,

with responders having a significantly improved overall and disease-free survival compared to nonresponders (Pezzi et al., 1989). The role of neoadjuvant chemotherapy in the management of cats and dogs with STS has not been investigated.

Postoperative Chemotherapy

Grade III cutaneous STSs are associated with an increased risk of metastasis (41% to 50%) and decreased survival times. Chemotherapy may have a role in these cases to delay or prevent the development of metastatic disease. However, metastasis usually occurs late in the course of disease (median time to metastasis of 365 days), and this may minimize the beneficial effects of postoperative chemotherapy in such cases. Studies investigating DOX-based protocols, single-agent ifosfamide and mitoxantrone, and dual agent DOX-ifosfamide in canine STSs have demonstrated no difference in disease-free interval or survival time between dogs receiving surgery alone and those receiving surgery and chemotherapy. In humans chemotherapy also does not affect overall survival time but may improve local tumor control. In one study postoperative DOX was not beneficial in increasing the metastasis-free interval or overall survival time in dogs with high-grade STSs of various locations (Selting et al., 2005). Situations in which postoperative chemotherapy should be considered include intraabdominal STSs (e.g., splenic sarcomas), metastatic disease, and dogs with histologic subtypes with a higher rate of metastasis (e.g., histiocytic sarcoma, hypodermal HSA [stage II or III], synovial cell sarcoma, rhabdomyosarcoma, and lymphangiosarcoma).

Intracavitary Chemotherapy

Marginal resection with implantation of an intracavitary biodegradable polymer of open-cell polylactic acid containing cisplatin has been reported with a 31% local tumor recurrence rate and a median time to recurrence of 640 days. This product is not available commercially, and local toxicity is common.

Metastatic Disease

Animals with metastatic disease should be managed palliatively rather than being treated with more aggressive curative-intent techniques such as surgery and/or RT. Pulmonary metastasectomy has not been evaluated for metastatic STS.

PROGNOSIS

Prognostic Factors for Local Tumor Recurrence

Prognostic factors for local tumor recurrence include tumor size, tumor location, tumor grade, and completeness of surgical excision. Tumors larger than 5 cm in diameter are more likely to develop local tumor recurrence. Site is also prognostic, with STSs located in superficial sites or the extremities having a better prognosis than tumors that are

deep, truncal, invasive, or close to the spinal cord. This is probably because location can affect ability to achieve complete surgical resection. Dogs with incomplete resection are over 10 times more likely to develop local disease recurrence. Tumor grade (low or intermediate grade are more favorable) and thickness of deep margin (>10 mm or at least one fascial plane nonadherent to the tumor) are prognostic factors for local recurrence. Tumors that are freely movable have a more favorable prognosis than those fixed to underlying tissues.

Prognostic Factors for Metastasis

The absence of metastatic disease at diagnosis is a positive prognostic factor. Mitotic rate has been shown to be significantly associated with the development of metastasis at a distant site. In one study dogs with 20 or more mitotic figures per 10 high-power fields were five times more likely to develop metastasis than dogs with less than 20 mitotic figures per 10 high-power fields. Degree of differentiation, tumor grade, and histologic type also significantly affected the likelihood of metastasis. Dogs with high-grade tumors have a higher risk of metastasis and death compared to dogs with low-grade tumors. Fewer than 10% of grade I STSs, 20% of grade II STSs, and 50% of grade III STSs undergo metastasis to the regional lymph nodes and lungs.

Prognostic Factors for Survival

Tumor-related deaths in animals with STS are usually caused by uncontrolled local disease. The median survival times for dogs with nonoral STSs treated with wide surgical resection or marginal surgical resection combined with adjuvant megavoltage RT are 1416 and 2270 days, respectively. Mitotic rate and percent tumor necrosis were significantly associated with survival time. Dogs with more than 10% necrosis are 2.8 times more likely to die of tumor-related causes than dogs with less than 10% necrosis. Dogs with 20 mitotic figures or more per 10 high-power fields were 2.6 times more likely to die of tumor-related causes than dogs with less than 20 mitotic figures per 10 high-power fields. Other prognostic factors for overall survival include tumor size, completeness of surgical resection, degree of differentiation, histologic tumor grade, and local tumor control.

CHAPTER 70

Canine Hemangiosarcoma

CRAIG A. CLIFFORD, *Tinton Falls, New Jersey*

LOUIS-PHILIPPE de LORIMIER, *Brossard, Québec, Canada*

A highly malignant tumor originating from endothelial cells, hemangiosarcoma (HSA) is diagnosed more frequently in dogs than in any other domestic species and has a high mortality rate. Representing approximately 2% of all canine tumors, HSA tends to affect older dogs of either sex, with a median age of 10 years at diagnosis. Although any breed can be affected, German shepherds, golden retrievers, and Labrador retrievers appear predisposed.

ETIOLOGY

The definitive etiology of canine HSA remains uncertain, although the strong breed association suggests a genetic predisposition. Chronic ultraviolet light exposure is a known risk factor for superficial (dermal) HSA in lightly pigmented short-haired breeds of dogs and similarly may be a risk factor for the conjunctival location according to a recently published retrospective study.

Research has shown overexpression of the oncoprotein STAT3 to be common in canine vascular tumors, with 100% of 22 HSA samples determined to be positive and with a higher percentage of positive cells in HSA than benign hemangiomas. Mutations in p53 and PTEN, two important tumor suppressor genes, were recently demonstrated in canine HSA and may also contribute in the malignant transformation of vascular endothelial cells.

Angiogenesis, the formation of new blood vessels, is a tightly regulated process involving both proangiogenic and antiangiogenic factors. This pathway is often dysregu-

lated in neoplasia via up-regulation of angiogenic factors and down-regulation of antiangiogenic factors. When compared to healthy dogs, vascular endothelial growth factor (VEGF), one of the most potent angiogenic factors, was shown to be elevated in the plasma and effusions of dogs with HSA. Angiopoietins, proteins playing a central role in the regulation of angiogenesis, were shown to be overexpressed in a canine splenic HSA sample when compared to normal spleen. Interestingly endostatin, a negative modulator of angiogenesis, was also recently found to be elevated in the serum of dogs with HSA. Evidence derived from in vitro research suggests that HSA cells are capable of producing a plethora of angiogenic factors such as VEGF, basic fibroblastic growth factor (bFGF), and the angiopoietins.

With the help of multiparameter flow cytometry, recently it was demonstrated that canine HSA originates from hematopoietic precursors with commitment to the endothelial lineage rather than from the malignant transformation of mature endothelial cells in the peripheral vasculature. The expression patterns of cell-surface markers observed in those multipotential bone marrow-derived stem cells with differentiation arrest at the hemangioblast stage may help in confirming the diagnosis of HSA, monitoring minimal residual disease, and obtaining an early diagnosis.

Ongoing research on the etiology of the disease, through collaborative efforts of the Dog Disease Mapping Project at the Broad Institute of the Massachusetts Institute of Technology, Harvard University, and a number of veterinary investigators aims to identify genetic mutations that increase susceptibility to development of HSA. Identification of the genetic basis of HSA will allow

for a better understanding of the biology of the disease and development of a deoxyribonucleic acid (DNA) test that eventually may advance preventative measures and novel targeted therapies.

BIOLOGIC BEHAVIOR AND PROGNOSIS

As an endothelial-derived tumor, HSA can develop anywhere in the body. The spleen, heart (right atrium or auricle), skin or subcutaneous tissues, and liver are the four most common primary sites. Other reported primary sites include kidney, muscle, bone, oral cavity, bladder, and lung. Metastatic dissemination and local infiltration occur early in disease, either hematogenously or via local seeding following tumor rupture. The lungs, liver, and omentum are the most frequent sites of dissemination. Hemangiosarcoma is recognized as the most common sarcoma to metastasize to the central nervous system (CNS). Certain primary tumor locations may be associated with a better prognosis; dermal, conjunctival and possibly subcutaneous HSA tend to have a lower metastatic rate than visceral tumors. Studies have demonstrated that higher clinical stage (Box 70-1) results in earlier metastasis and shorter survival time for splenic and subcutaneous HSA. When advanced metastatic disease is present, it is often impossible to identify the primary site, and the prognosis is unsurprisingly poor to grave, although occasional responses to therapy have been observed.

DIAGNOSIS AND STAGING

Since clinical stage affects prognosis and HSA is a highly metastatic cancer, complete clinical staging is highly recommended at diagnosis when the patient is sufficiently stable. In cases in which emergency surgical intervention

Fig. 70-1 Left lateral digital radiograph of a dog with pulmonary metastasis from splenic hemangiosarcoma, demonstrating the typical interstitial miliary pattern.

must be performed to save the patient's life, certain staging procedures may have to be postponed temporarily. As previously mentioned, metastatic disease frequently affects the lungs; liver; omental surfaces; and occasionally soft tissues, adrenal glands, and the CNS. Although it is not considered metastatic dissemination, it is known that approximately 25% of dogs with HSA in one location (e.g., spleen) also have another primary HSA in a second site (e.g., right atrium), a process described as metachronous disease.

As a result, complete clinical staging should include three-view thoracic radiographs, abdominal ultrasonographic study, and multiple image-plane echocardiography, in addition to standard blood work. Although the typical appearance of measurable pulmonary metastatic disease is that of a coalescing miliary pattern, either nodular or generalized miliary interstitial patterns also can be observed on occasion (Fig. 70-1). Abdominal ultrasonography is a fairly sensitive routine imaging technique permitting the detection of splenic or hepatic lesions, occasionally of omental nodules as well, and in most cases identifies free abdominal fluid when present. Echocardiography remains the method of choice to identify right atrial masses; these are more easily identified when at least some degree of pericardial effusion is present and when multiple right and left-sided image planes are obtained by experienced examiners. Although urinalysis and serum biochemistry rarely help in the diagnosis of HSA, the complete blood cell count typically has changes that may suggest a microangiopathic process, including the presence of regenerative anemia, thrombocytopenia, and fragmented red blood cells (schistocytes). In addition, when the spleen is severely affected, a deficient reticuloendothelial system will permit higher numbers of metarubricytes (nucleated red blood cells) to appear in the peripheral blood.

In select cases additional imaging techniques may be required for identification of suspect metastasis based on physical examination findings (e.g., suspect bone or CNS metastasis). Advanced imaging in the form of computed tomography (CT) or magnetic resonance imaging (MRI) is recommended for invasive subcutaneous or

Box 70-1

Clinical Staging System for Hemangiosarcoma

Primary Tumor (T)

- T0: No measurable tumor
- T1: Tumor less than 5 cm in diameter, confined to primary site; does not invade beyond dermis (cutaneous HSA)
- T2: Tumor 5 cm or greater in diameter, or ruptured; invades subcutaneous tissues (cutaneous HSA)
- T3: Tumor invades adjacent structures; invades into the underlying muscle (cutaneous HSA)

Regional Lymph Nodes (N)

- N0: No regional lymph node involvement
- N1: Regional lymph node involvement
- N2: Distant lymph node involvement

Distant Metastasis (M)

- M0: No measurable distant metastasis
- M1: Detectable distant metastasis
- Stage I: T0 or T1, N0, M0
- Stage II: T1 N1 or T2 N0, M0

HSA, Hemangiosarcoma.

intramuscular HSA to assess invasiveness and plan surgical resection and/or radiation therapy, if indicated. In addition, recent work has shown that imaging modalities such as MRI and CT carry a high sensitivity and specificity in discriminating benign from malignant splenic and hepatic lesions. Furthermore, recently published and ongoing studies are confirming the increased sensitivity of thoracic CT for early pulmonary metastasis detection. As the routine use of such diagnostic techniques increases in veterinary medicine, these studies may be incorporated more routinely in the thorough staging of dogs with HSA.

The definitive diagnosis of HSA is only confirmed with histopathology. It is crucial to remember that no imaging technique can confirm with certainty that the observed lesion is in fact HSA. Therefore no patient with hemoabdomen should be euthanized based on a splenic mass that "is consistent with HSA," especially since nonmalignant splenic lesions, including hematomas and hemangiomas, appear identical in many cases, bear a very good prognosis with splenectomy alone, and are often diagnosed in breeds known to be overrepresented for HSA. The precise number of patients with hemoabdomen and associated malignancy has varied in different reports. Several retrospective studies have shown that for splenic nodules a third to 50% are benign and curable with a sole splenectomy. However, a recent study of patients presenting with a nontraumatic hemoabdomen noted that 80% were secondary to visceral neoplasia, of which 70% were confirmed as HSA. Although cytology is a noninvasive and clinically valuable technique for the diagnosis of cancer in general, the diagnostic yield for HSA is reported to be low (25%).

One possible way to improve the prognosis of canine HSA may come in the form of earlier detection. The current standard for diagnosing HSA remains histopathology of measurable lesions usually after metastatic dissemination has already occurred; however, new detection methods eventually may help obtain an early diagnosis for high-risk dogs. One such method involves flow cytometry of peripheral blood to identify cells of primitive endothelial lineage, coexpressing certain cell surface markers, detected in higher numbers in dogs harboring HSA than in healthy controls or dogs rendered free of measurable HSA following surgical excision.

The current research aiming to identify causative mutations of certain genes eventually may enable the development of DNA tests capable of identifying susceptible individuals and those that may pass these genes to their progeny. Such tests would allow owners and veterinarians to follow susceptible dogs more closely for tumor occurrence, possibly before life-threatening complications occur.

TRADITIONAL THERAPY

Traditional therapy for HSA, as for other cancers, involves surgery, radiation therapy, and systemic cytotoxic chemotherapy, alone or in a multimodality setting.

Surgery

Splenectomy, liver lobectomy, excision of dermal or subcutaneous masses, and right auriculectomy all have been

reported. Such surgeries are performed to remove all macroscopic tumors and prevent further risk of acute hemorrhage, establishment of disseminated intravascular coagulation, or death. Surgery alone for splenic, cardiac, subcutaneous, or hepatic HSA has yielded unsatisfactory results and is generally considered purely palliative, with median survival times (MSTs) generally averaging 1 to 3 months. A recent study of 23 dogs with cardiac HSA reported a MST of 43 days (n=8) and 118 days (n=15) following resection of right atrial or auricular HSA, respectively. The MST was significantly prolonged in eight dogs receiving chemotherapy (175 days) when compared to 15 dogs treated with surgery alone (42 days). Pericardiectomy via thoracotomy or thoracoscopy can alleviate life-threatening cardiac tamponade, but alone it is unlikely to significantly prolong survival. Surgical resection of superficial dermal or conjunctival HSA often results in prolonged survival times because of the lower metastatic rate observed with these primary locations.

Chemotherapy

Doxorubicin (DOX)-based adjuvant chemotherapy, with or without the addition of cyclophosphamide or vincristine, has provided the best survival times to date. Common protocols include single-agent DOX; DOX and cyclophosphamide (AC protocol); and vincristine, DOX, and cyclophosphamide (VAC protocol). Survival times ranging from 140 to 202 days have been reported for the various DOX-based protocols; however, no protocol is regarded as clearly superior. In an attempt to improve on the MST, a dosage-intensive protocol with every-other-week DOX administration and intracavitary chemotherapy administration with the liposome-encapsulated form of DOX (Doxil) were investigated. Unfortunately these did not result in significant survival benefit. Ifosfamide, an alkylating agent with therapeutic activity in human sarcomas, was administered following splenectomy in six dogs with HSA, resulting in a MST of 147 days. When a combination of ifosfamide and DOX was recently evaluated in the adjuvant setting on 27 dogs with HSA, a disappointing MST of 149 days was obtained. Although the benefits of adjuvant chemotherapy on survival times are well recognized, additional or novel therapeutic modalities are clearly needed.

Radiation Therapy

There is a paucity of published information regarding the use of radiation therapy for canine HSA. However, anecdotal clinical responses and quality-of-life improvements have been observed when coarse fractions of megavoltage radiation therapy are delivered (once or twice weekly) to invasive and nonresectable subcutaneous or intramuscular HSA lesions. In such cases radiation therapy is considered palliative, decreasing pain and bruising and occasionally resulting in tumor shrinkage, and generally is combined with systemic DOX-based chemotherapy.

NOVEL THERAPY

Since the combination of traditional therapeutic modalities has reached a plateau unlikely to be surpassed, with

MSTs averaging 6 to 7 months, new therapies are awaited impatiently. The growing body of knowledge on the molecular alterations observed in canine HSA cells may hopefully unveil numerous novel targets.

Immunotherapy has long been a field of active research, and an aggressive and rapidly progressing cancer such as HSA provides a great opportunity for even small improvements to be detected. Although initial studies evaluating nonspecific immunotherapy had failed to provide similarly positive outcomes, a randomized, prospective evaluation in canine HSA patients combining the AC protocol with liposomal muramyl tripeptide phosphatidylethanolamine (L-MTP-PE), a synthetic macrophage activator derived from mycobacterial cell wall, resulted in the only published study reporting a MST significantly superior to traditional chemotherapy alone (273 days). Although this study firmly established a role for immunotherapy in treating canine HSA, L-MTP-PE is not commercially available. Recently an unpublished pilot study using an intraperitoneally administered allogeneic HSA vaccine demonstrated encouraging results, conferring an MST greater than 7 months in seven dogs with stage III HSA receiving the vaccine in combination with standard chemotherapy. Further studies are ongoing.

Antiangiogenic therapy is an important field of investigational cancer therapy in humans and is the subject of numerous ongoing clinical studies on canine HSA. Systemic administration of interleukin-12 (IL-12), a cytokine known to possess potent antiangiogenic properties, inhibited the growth of canine HSA in a murine model. Studies in dogs evaluating IL-12, interferon- α -2a, thrombospondin-1, protease inhibitors, and thalidomide eventually may demonstrate benefits in terms of improved MST, and the results are highly anticipated. Although novel humanized monoclonal antibodies directed against certain angiogenic proteins (e.g., bevacizumab targeting VEGF) may not be practical for use in dogs because of the induction of neutralizing canine antihuman antibodies, the ongoing research on small-molecule inhibitors targeting the same signaling pathways (VEGF, bFGF, integrins) raises cautious optimism for eventual application in the veterinary field.

In contrast to most canine carcinomas evaluated to date, it appears that canine HSA typically does not overexpress COX-2. However, because nonsteroidal drugs have also demonstrated clinical efficacy in certain non-COX-2 overexpressing tumors, it is conceivable that incorporating a COX-2 inhibitor to standard therapy might prolong the survival time of dogs with HSA. However, a recently completed but unpublished prospective study found no overall improvement in survival when a COX-2 selective inhibitor was coadministered with adjuvant DOX therapy in dogs with splenic HSA.

As previously stated, mutated tumor suppressor genes may contribute to malignant transformation. Interestingly it is also possible for such genes to be transiently silenced

through epigenetic changes, opening the way for therapy targeting such reversible alterations. Although occasional reports of long-term survival following surgery alone have been reported, a published case report described a dog surviving in excess of 1000 days following splenectomy for HSA after receiving a histone deacetylase (HDAC) inhibitor as the sole adjuvant therapy. This encouraging outcome and further large-scale prospective in vivo studies with HDAC inhibitors hold promise for dogs with aggressive malignancies such as HSA.

Finally the use of traditional chemotherapy agents can also be revisited through novel methods or schedules of administration. A study evaluating concurrent systemic and inhalational therapy with DOX demonstrated encouraging results in diminishing pulmonary metastasis from HSA. "Metronomic" (continuous, low-dose) dosing of traditional cytotoxic chemotherapy agents is another new approach. The therapeutic target is then shifted from the cancer cells to the endothelial cells by administering frequent low doses of chemotherapy. By so doing, the common problems of toxicities and drug resistance can largely be avoided. Ongoing clinical studies aim to evaluate the potential benefit of low-dose metronomic chemotherapy on measurable HSA and in the adjuvant setting.

Feline Vaccine-Associated Sarcomas

MATTIE J. HENDRICK, *Philadelphia, Pennsylvania*

A. ELIZABETH HERSHEY, *Phoenix, Arizona*

Since 1991 there have been several reports supporting a strong association between the administration of vaccines, particularly feline leukemia and rabies, and the subsequent development of sarcomas in cats at the site of vaccination. Although these sarcomas are uncommon, with estimates of their occurrence ranging from 1 in 1,000 to 1 in 10,000 cats receiving vaccinations, they are aggressive, resulting in significant morbidity and mortality. Most tumors have proved resistant to standard treatment modalities, and many cats have multiple recurrences, with euthanasia as the final outcome. Despite many years of epidemiologic and investigational research, feline vaccine-associated sarcomas (VASs) remain a significant problem in veterinary medicine.

CLINICAL APPEARANCE AND BEHAVIOR

Most VASs arise in the interscapular subcutis, along the dorsal and lateral thorax and flank, and in the musculature of the thigh or more distal limb, reflecting common vaccination sites. Recommendations by the Vaccine-Associated Feline Sarcoma Task Force (VAFSTF)* and other veterinary organizations to use the distal limbs rather than the interscapular region for vaccination have been followed by practicing veterinarians with mixed success. Typical tumors are grayish-white, firm, well demarcated, and partially encapsulated. Most tumors are larger than 4 cm in diameter when found by the owner or veterinarian and have a necrotic center, giving them a cystic appearance. Despite the circumscribed gross appearance of the tumor, there are often “tongues” of tumor extending away from the mass along fascial planes, most clearly seen by computed tomography or magnetic resonance imaging. The majority of VASs are fibrosarcomas, but malignant fibrous histiocytomas (also called myofibrosarcomas or myofibroblastic sarcomas), osteosarcomas,

chondrosarcomas, rhabdomyosarcomas, myxosarcomas, and liposarcomas have also been reported. Histologically most VASs have a high degree of nuclear pleomorphism, cellular atypia, and multinucleated giant cells. Many but not all have peripheral aggregates of lymphocytes and macrophages. In some the macrophages contain a globular grayish-brown material that has been shown to be aluminum, a common adjuvant used in feline vaccines.

In one retrospective study (Hendrick et al., 1994), 62% of the tumors recurred following excisional biopsy, most within 6 months. A total of 22% of cats had VASs recur two, three, or four times. Based on published reports, the metastatic rate of VAS is variable, ranging from 0% to 28%, the higher rates occurring in cats that had repeated recurrences or radiation therapy (RT).

PATHOGENESIS

Based on morphologic and immunohistochemical evidence, VASs appear to arise from primitive mesenchymal cells that have features of fibroblasts and myofibroblasts. The exact origin of myofibroblasts is controversial, but many believe they represent a “transitional stage” through which fibroblasts or some other primitive mesenchymal cells pass during the process of wound healing. Injection of vaccines commonly results in a localized granulomatous and lymphocytic reaction that varies in severity and duration, depending on the vaccine and adjuvant.

The increased incidence of fibrosarcomas in cats began in the late 1980s, shortly following the introduction and widespread use of killed aluminum-adsorbed rabies and leukemia virus vaccines not previously used in the cat. Macy (1999) has documented that these vaccines consistently produce palpable inflammatory masses at the site of injection in cats. Hypothetically VASs may arise from inappropriate or overzealous inflammatory or immunologic reactions associated with the presence of vaccine components in vaccination sites that lead to uncontrolled proliferation of fibroblasts and myofibroblasts. Despite the importance of feline leukemia virus (FeLV) and feline sarcoma virus (FeSV) in many diseases and neoplasms in cats, these viruses do not appear to play a role in the pathogenesis of VASs (Ellis et al., 1996).

Research in the senior author's laboratory and by other investigators has focused on growth factors and oncogenes as likely players in this neoplastic transformation. Many studies and animal models support the hypothesis that growth factors promote neoplastic transformation.

* The Vaccine-Associated Feline Sarcoma Task Force is a combined effort of the American Veterinary Medical Association, the American Animal Hospital Association, the American Association of Feline Practitioners, and the Veterinary Cancer Society. Its membership is composed of representatives from the aforementioned groups, veterinary researchers and clinicians, and representatives from the U.S. Department of Agriculture and the Animal Health Institute. The guidelines are based on discussions and materials provided by this group, the Academy of Feline Medicine, and the California Veterinary Medical Association.

A large percentage of human tumors have been shown to have receptors for growth factors that they themselves produce in an abnormal or autonomous fashion. Termed *autocrine stimulation*, I and others have documented this phenomenon in feline VAS, using immunohistochemical and molecular methods. Specifically platelet-derived growth factor (PDGF) and its receptor are overexpressed in feline VAS and in cultured cell lines from these tumors. McEwen and later Vail and associates (Katayama et al., 2004) showed that the use of a tyrosine kinase inhibitor blocks signaling through the PDGF receptor, resulting in decreased viability of the cultured sarcoma cells, inhibition of tumor growth in nude mice, and enhancement of the sensitivity of the cultured cells to chemotherapeutic agents. Last, dysregulation of p53, a tumor suppressor protein, appears to be a feature of many feline fibrosarcomas, including those associated with vaccination (Hershey et al., 2005). Clearly differences in host genome and alterations in p53 and growth factor expression play a role in the pathogenesis of these tumors and should be the focus of continuing research.

TREATMENT

Effective treatment of VAS resulting in long-term control remains challenging. Although surgery remains the mainstay of treatment, by itself it rarely achieves long-term tumor control. Completeness of surgical excision does not always guarantee tumor control because tumors can recur in the face of histologically “complete” surgical excision. Whether this tumor recurrence represents true local recurrence or the effect of “field cancerization” remains unclear. More aggressive or radical first excision of VAS is an important first step in achieving long-term tumor control (Hershey et al., 2000). In one study radical first excision of VAS yielded a longer median disease-free interval (DFI) (325 days) when compared with marginal first excision (79 days). In addition, cats with tumors located on the limbs had a longer DFI (325 days) than cats with tumors located in other sites (66 days). This reflects the ability of radical excision (i.e., amputation) to be achieved should a VAS occur. However, few cats (13.8%) that received only surgical treatment had long-term control of greater than 2 years. In multiple studies the recurrence rate was higher for cats with multiple surgeries than cats that had only one surgery (Hershey et al., 2000, Cohen et al., 2001). In addition, tumors have been noted to recur in shorter intervals with each successive surgery. Thus adjuvant treatments with RT and/or chemotherapy are warranted in most patients.

Chemotherapy with doxorubicin (DOX) and Doxil (liposome-encapsulated doxorubicin) has been evaluated objectively as an adjuvant to surgery in cats with VAS (Poirier et al., 2002). Cats receiving either DOX or Doxil after surgery had a significantly longer DFI compared to historical controls receiving surgery alone (388 versus 94 days). Cats with complete excision had a longer DFI (449 days) than cats with incomplete excision (281 days). No significant difference was noted in the outcomes between the two chemotherapy agents. DOX with or without cyclophosphamide may also be beneficial in treating

macroscopic disease, providing palliation, or making some nonresectable tumors amenable to surgery (Poirier et al., 2002, Barber et al., 2000).

Carboplatin may also be a useful agent in the treatment of VAS. Six of 16 cats with measurable VASs treated with carboplatin experienced a partial response. In addition, cats treated with carboplatin concomitant with preoperative RT in one study had a longer median DFI compared to other chemotherapy treatments (Kobayashi et al., 2002). This may be caused by the effect of carboplatin as a radiation sensitizer when given in conjunction with RT. Other potentially effective drugs include mitoxantrone, ifosfamide, and lomustine.

Several studies have reported treatment outcomes of multimodality therapy combining surgery, RT, and chemotherapy. Outcomes have been similar between the studies for preoperative and postoperative RT; advantages can be argued for both. With no clear improvement in DFI, the decision for preoperative or postoperative RT should be made on a patient-by-patient basis. The use of chemotherapy concomitant with RT did not significantly influence DFI in any study. However, in one study overall survival times were longer with use of carboplatin in conjunction with RT than with other chemotherapies (Kobayashi et al., 2002). No direct comparisons have been made between combined surgery and RT versus combined surgery and chemotherapy. A comparison of treatment outcomes is reported in Table 71-1.

The efficacy of RT without chemotherapy in the treatment of VAS is unclear. Given the potential for metastasis in VASs, systemic therapy in conjunction with local therapy is warranted.

In summary, surgery as a sole therapy results in a high rate of local recurrence, except in tumors of the distal limb in which amputation is performed. The high frequency of recurrence in cats with histologically complete surgical resection indicates that adjuvant therapy should be considered in all cats with VASs. Combined therapy with RT and/or chemotherapy results in an improved DFI over surgery alone. However, in spite of combined therapies, long-term control is difficult to achieve, and attention must be directed at prevention of these tumors.

PREVENTION

The most important recommendation in the prevention of VAS is not to overvaccinate. One study clearly shows an increased incidence of VASs with increased number of vaccines administered (Kass et al., 1993). Vaccination should be viewed as a medical procedure similar to any other medical procedure and performed based on the medical needs of the individual patient. Veterinarians and cat owners must decide the relative risk of disease for individual cats and make appropriate decisions regarding vaccination. FeLV vaccine should not be administered indiscriminately since the epidemiologic data suggest it may be the most common cause of VAS in cats. There is an age-related susceptibility to FeLV, with kittens being at most risk of persistent infection. The risk of infection with FeLV decreases with age, with fewer than 15% of cats over 1 year of age becoming infected when challenged. The decision to vaccinate for FeLV should be based

Table 71-1

Treatment Outcomes For Vaccine-Associated Sarcomas

Study	Treatment	No. of Cats	DFI	OST	RR (%)	RM (%)	Comments
Cronin, Page, and Thrall 1998	Preop RT, sx \pm DOX	33	398	600	45	24	Outcome influenced by completeness of excision; use of chemo did not influence outcome
Hershey et al., 2000	Surgical excision	61	94	576	86.2	22.5	Radical excision (i.e., amputation) improves DFI
Bregazzi et al., 2001	Sx, postop RT \pm DOX	25	661 (+ chemo) NR (- chemo)	674 (+ chemo) 842 (- chemo)	28	0	No significant difference in outcome with use of chemo
Cohen et al., 2001	Sx, postop RT \pm DOX/ cyclophosphamide	78	405	730	41	12	Use of chemo not associated with RR, RM, OST; extent of excision not associated with RR
Kobayashi et al., 2002	Preop RT, sx \pm carboplatin	92	584	Not evaluated	37	21.7	Completeness of excision related to DFI
Poirier et al., 2002	Sx + DOX or Doxil	75	388	846	44	5	No difference between Doxil and DOX; renal toxicity noted with Doxil when dose escalated
Martano et al., 2005	Preop DOX + sx sx alone	49	NR	NR	40.8	12	No significant difference between groups
		20	NR	NR	35	10

on the lifestyle of the cat, and few clinicians currently recommend FeLV vaccine for strictly indoor cats in a closed household. Rabies vaccination recommendations should follow state and local regulations.

It must be stressed that individual cats be vaccinated no more frequently than necessary and only against infectious diseases to which the individual has a realistic risk of exposure. Annual revaccination may not always be needed and may increase the risk that sarcomas will develop at vaccination sites. In one study many of the commercial vaccines had a duration of immunity longer than 1 year (Scott and Geissinger, 1997), supporting an every-3-year-program of vaccination.

The use of monovalent versus polyvalent vaccines is controversial. In one study (Kass, 1993) there was a significant increase in the risk of sarcoma development with increasing numbers of vaccines. However, Hendrick and associates (1994) found no association between vaccine site tumors and the number of vaccines administered simultaneously. Although conflicting results exist, it seems prudent that vaccines be injected at different sites and that polyvalent vaccines not be used.

The use of vaccines containing aluminum adjuvants is controversial. Aluminum-adjuvanted vaccines are the most consistent producers of vaccine site inflammation, a key factor in the development of VAS. The canary pox vectored recombinant feline rabies vaccine creates virtually no cellular infiltrate at the site of injection (Macy and Chretien, 1999). However, this vaccine must be administered annually rather than every 3 years. It seems logical to think there would be less risk if a less inflammatory product were administered less frequently. However, it is still not known whether other vaccine components contribute to the formation of VAS.

Current recommendations are for administration of vaccine as distally on the limb as possible. The site of administration does not likely affect the development of a sarcoma. However, if the sarcoma is located on the distal limb, the tumor may be identified at a smaller size, and amputation may allow better tumor control. In one study (Hershey et al., 2000) cats that had sarcomas in the distal portion of the limb treated by amputation had a longer median DFI than cats with sarcomas excised from other sites.

The following are guidelines based on the recommendations of the VAFSTF and the American Association of Feline Practitioners:

1. Veterinarians should adopt a standardized protocol for vaccination sites and document the locations of each injection, type of vaccine, and manufacturer or serial number.
2. Vaccines containing antigens limited to panleukopenia virus, feline herpesvirus type-1, and feline calicivirus with or without *Chlamydia* antigens should be administered on the right shoulder.
3. Vaccines containing rabies virus antigen, with or without any other antigen, should be administered on the right hind limb as distally as possible.
4. Vaccines containing FeLV antigen, with or without any other antigen except rabies virus antigen, should be administered on the left hind limb as distally as possible.

OWNER EDUCATION

Although the risk of VAS occurrence is real, owners should be educated as to the relative risk of VAS development

versus the risk of serious, preventable infectious disease, allowing them to make informed decisions about vaccination administration and frequency. Furthermore, as with most tumors, early detection and appropriate therapy have the potential to lead to improved outcomes. As previously mentioned, almost all cats develop some degree of inflammatory reaction at the site where a vaccine is administered. It is useful to have criteria for when a lump at a vaccine site is a cause for concern. A helpful mnemonic for owners is the so-called "3-2-1 rule." The veterinarian should be notified if the lump persists for more than 3 months following vaccination, if it exceeds 2 cm in diameter at any time, or if it is continuing to enlarge 1 month after vaccination. Vaccine-site lumps meeting any of these criteria should be investigated by incisional or excisional biopsy.

Canine Lymphoma

SUSAN E. LANA, *Fort Collins, Colorado*

ANNE AVERY, *Fort Collins, Colorado*

Canine lymphoma is the most common hematologic malignancy encountered in both the specialty and general practice setting. Treatment with chemotherapy is the standard of care for this disease, with multidrug protocols providing 80% to 90% remission rates. In spite of this high response rate, canine lymphoma is not considered curable; average reported survival times are in the 12- to 14-month range (Vail, 2001). Over the last several years relatively little progress has been made in improving these outcomes; although, as we learn more about the genetic and molecular basis of canine lymphoma, there is hope that this will change. The purpose of this chapter is to discuss recent trends and possible advancements in the treatment, diagnosis, and prognosis for canine lymphoma. Extensive reviews about specific drug protocols, rescue strategies, and atypical variants of canine lymphoma can be found elsewhere in the literature (Vail, MacEwen, and Young, 2001).

VARIATIONS ON A THEME: THE CHOP PROTOCOL

Most veterinary oncologists agree that the best response rates and most durable remissions are achieved with a combination of drugs given in sequence over a period of weeks. Currently the drugs most commonly used are vincristine (Oncovin), cyclophosphamide (Cytosan), doxorubicin (Adriamycin), and prednisone. This combination of drugs has been the mainstay of treatment for human non Hodgkin's lymphoma in a protocol commonly referred to as CHOP (C, cyclophosphamide; H, hydroxydaunorubicin [the initial name for doxorubicin hydrochloride]; O, Oncovin, P, prednisone). The CHOP-based protocol commonly used at our institution can be found in Table 72-1. Attempts have been made to vary drug sequence and dose to improve outcome, but no clear clinical benefit has been seen with these strategies. L-asparaginase (L-aspar) is also included in many published veterinary protocols. Because of unforeseen drug availability problems, the benefit of using L-aspar in combination with CHOP has been called into question. In one large case study evaluating 115 dogs with lymphoma, no increase in first remission duration, overall response rates, overall survival times, or toxicity was seen with the addition of L-aspar to the treatment protocol (MacDonald et al., 2005). Because of this, many oncologists now reserve the use of L-aspar for a rescue or salvage setting. Recent studies evaluating the CHOP protocol have focused on specific aspects, including

adding radiation therapy, increasing dose intensity, and investigating discontinuous protocols that do not involve long-term maintenance therapy. These are discussed in the following paragraphs.

Maintenance versus No Maintenance

Traditionally treatment of lymphoma in both humans and dogs has at one time or another involved induction protocols followed by a less intense, protracted maintenance schedule lasting in some cases for years. Many original CHOP-based protocols described for the treatment of canine lymphoma continued for as long as 104 weeks. Current trends have shown that shortened, discontinuous protocols without a maintenance phase have resulted in similar overall remission rates and survival times. The advantages of the shortened treatment schedule include decreased time in the veterinary clinic; decreased cost to the owner; and possibly a decrease in potential late effects of long-term chemotherapy exposure, although the risk of this in veterinary medicine is low because of the poor cure rate and shortened life span. Garrett and associates (2002) showed that a 25-week protocol resulted in no significant difference in disease-free interval (DFI) or survival when compared to a 104-week protocol with a maintenance phase. Median DFI and survival of the study group compared to the maintenance group were 282 and 397 versus 220 and 303 day, respectively. In another study a 12-week CHOP-based protocol was evaluated in 77 dogs, and a median first complete remission of 243 days reported (Simon et al., 2006).

Dose Intensification and Bone Marrow Transplantation

Dose intensification is another strategy used in an attempt to improve outcome for canine lymphoma. With an increased dose an increase in toxicity is also expected. In one study a CHOP-based protocol was dose intensified by increasing the dose of both cyclophosphamide (250mg/m² vs. 200mg/m²) and doxorubicin (37.5mg/m² vs. 30mg/m²). No DFI or survival benefit was found compared to a longer maintenance protocol, and the number of patients that died of toxicity in the dose-intensified group was 13 of 49 (27%) compared to 2 of 55 (4%) of dogs treated with traditional doses (Chun, Garrett, and Vail, 2000). Without a benefit in outcome the increase in toxicity is unacceptable to most pet owners. Another approach used successfully in humans is high-dose ablative chemotherapy

Table 72-1

Example of a CHOP-Based Protocol

DRUG	DOSE	WEEK																
		1	2	3	4	6	7	8	9	11	12	13	14	16	17	18	19	
Vincristine	0.5-0.7 mg/m ² IV	X		X		X		X		X		X		X		X		
Cyclophosphamide	250 mg/m ² IV* or PO		X				X				X				X			
Doxorubicin†	30mg/m ² IV				X				X				X				X	
Prednisone‡	2mg/kg PO q24h	X	X	X	X													

IV, Intravenously; PO, orally.

* Furosemide (1 mg/kg IV) is given concurrently with IV cyclophosphamide

† Decrease dose to 1 mg/kg in dogs < 15 kg in body weight

‡ Week 1: 2 mg/kg PO q24h; week 2: 1.5 mg/kg PO q24h; week 3: 1 mg/kg PO q24h; week 4: 0.5 mg/kg PO q24h, then discontinue.

followed by some form of bone marrow transplant as a rescue from toxic side effects. Although this type of approach currently is not feasible for general practice, a variant has been reported in a small number of canine lymphoma patients with variable outcomes. Twenty-eight dogs with lymphoma underwent nonmyeloablative but dose-intense (up to 500mg of cyclophosphamide per square meter) chemotherapy following a standard CHOP-based induction. They then received autologous bone marrow rescue. Toxicity from this approach was manageable and acceptable, and some patients achieved a long-term remission (Frimberger et al., 2006). Further investigation is needed to determine the subgroup of patients that might benefit from this approach.

Radiation Therapy

Lymphoid tissue is very sensitive to the effects of radiation therapy (RT). In the past RT generally has been used in a regional or local fashion to augment systemic chemotherapy (see Chapter 67). Recent studies have explored using a whole-body RT approach given in half-body increments to take advantage of the fact that relatively low doses of radiation are effective against lymphoma and can have minimal negative effect on the patient. A pilot study and a larger case series (Gustafson et al., 2004; Williams et al., 2004) have explored an approach combining CHOP-based chemotherapy with whole-body RT using two consecutive 4-Gy fractions to the cranial half of the body followed 3 to 4 weeks later by the same treatment to the caudal half of the body. Preliminary data from these studies have shown that toxicity associated with the addition of RT has been minimal and that remission and overall survival may be improved. One caveat to these results is that the patients who seem to benefit most are those that have already achieved a complete response with chemotherapy and perhaps would have done well in spite of additional treatment. Further investigation combining these two modalities is definitely needed to show sustained benefit of this combination approach.

DIAGNOSIS AND PROGNOSIS

The diagnosis of lymphoma often can be made by aspiration cytology alone, but in relying solely on cytology a significant amount of prognostic information may be lost. For the most prognostic power, the diagnosis ideally is made using the combination of biopsy and immunophenotyping. Clonality testing, which detects as few as 1 malignant cell in 100 normal cells, can be used as an aid to the diagnosis when histology or cytology is equivocal (Avery and Avery, 2004).

Multiple studies at different institutions spanning many years have demonstrated that, when taken as a whole, T cell lymphomas have a significantly worse prognosis than B cell lymphomas. However, recently increasing attention has been devoted to using combination of histology and immunophenotype in determining prognosis. When both are considered, indolent lymphomas of both B and T cell immunophenotypes have a comparatively favorable prognosis, with some evidence that indolent T cell lymphomas (referred to as "T zone" or "small clear cell" lymphomas) may have a better prognosis (Valli et al., 2006). Thus, if prognosis is an important consideration in the decision of whether or not to treat, it may be important to determine both immunophenotype and histologic classification.

Dogs with indolent forms of lymphoma may have a long history (up to a year and longer) of lymphadenopathy, which is classified as lymphoid hyperplasia or atypical lymphoid hyperplasia by cytology and/or histology. When such equivocal results are obtained, there are several ways to distinguish reactive hyperplasia from neoplasia. All rely on the general principle that neoplasia involves expansion of a single clone and therefore manifests as a homogeneous population of lymphocytes, whereas reactive hyperplasia generally involves multiple lymphocyte subsets. Immunophenotyping on formalin-fixed, paraffin-embedded tissue sections, using anti-CD3 (to stain T cells) and anti-CD79a (to stain B cells), is one widely available technique that may in some cases help pathologists recognize neoplasia in equivocal samples.

Alternatively fresh lymph node aspirates may be analyzed by flow cytometry. Box 72-1 lists laboratories that currently offer flow cytometry as a commercial service. This technique establishes if the lymphocyte population is dominated by a single lymphocyte phenotype (neoplasia) or heterogeneous expansion (reactive hyperplasia). It has the advantage that a large panel of antibodies can be used on freshly aspirated samples but the disadvantage of not being able to examine cells within the context of the lymph node architecture. Clonality assessment is the most sensitive way to detect neoplastic lymphocytes

within a lymph node (see Box 72-1 for the laboratory that currently offers this test commercially). This is a polymerase chain reaction (PCR)-based assay (PCR for antigen receptor rearrangements [PARR]) that is best carried out on deoxyribonucleic acid from any source other than paraffin-embedded samples (fresh aspirates, stained or unstained cytology preparations, peripheral blood, effusions). Detection of neoplastic cells relies on the observation that the genes for antigen receptors (immunoglobulin and T cell receptor genes for B and T cells, respectively) are different in length and sequence in each lymphocyte. PCR amplification of gene segments from these antigen receptor genes results in a single-sized product if the lymphocytes present are derived from the same clone (neoplasia). Multiple PCR products are amplified if the lymphocytes are heterogeneous (reactive). In practice the kinetics of the PCR reaction allow for the detection of as few as 1 in 100 neoplastic cells in cases of early neoplasia (Burnett et al., 2003). This makes the assay useful for detecting neoplasia before it is evident histologically or cytologically. It is important to note that the conditions for the assay have a profound effect on the sensitivity and specificity of the results; therefore each laboratory conducting the assay should report these numbers when they report results to allow proper interpretation of the findings.

In addition to immunophenotype and histologic subtype, clinical stage has consistently been demonstrated to correlate with outcome. Multicentric lymphoma is the most common form in dogs, and these cases usually present as stage III or higher. Perhaps the most consistent prognostic factor associated with staging is the substage; patients with substage a disease (no systemic signs) have considerably better survival times than patients with substage b disease (systemic signs).

Although clinical staging, histology, and immunophenotyping should be used routinely for determining diagnosis and prognosis, a host of other factors have been investigated for their ability to contribute to prognosis and in the future may be used more routinely. These include various markers of proliferation, including argyrophilic nucleolar organizer region (AgNOR) staining, serum levels of thymidine kinase, expression of the Ki-67 marker, serum levels of circulating endothelial markers and matrix metalloproteases, and additional immunophenotypic markers. It seems likely that these will be most useful when applied within a particular histologic and immunophenotypic subclassification of lymphoma.

Although many of these methods may be useful for the diagnosis and prognosis of lymphoma, at present there are no objective tests beyond clinical measures of disease burden that allow clinicians to follow patients in remission or to determine when a patient has come out of remission. Flow cytometry does not appear to be useful, and cytology often can be equivocal and subjective. The assessment of remission currently is based primarily on physical examination findings and cytology. The PARR assay may prove to be useful in this regard because it can give a quantitative determination of tumor burden and can detect relatively small numbers of tumor cells in the blood and lymph nodes. The use of this assay to monitor patients after treatment is currently under investigation.

GENETIC DISCOVERIES IN CANINE LYMPHOMA

In human oncology lymphomas are further categorized by cytogenetic abnormalities and the expression of oncogenes. Histologically and immunophenotypically homogeneous groups of human lymphomas have been shown to be remarkably heterogeneous in the nature of the chromosomal rearrangements they harbor, and these in turn can be used to further subdivide this tumor into prognostically meaningful subsets. For example, human diffuse large B cell lymphoma is considered to be analogous to the most common form of canine lymphoma. Within this tumor type a combination of cytogenetic studies to identify chromosomal translocations and gene expression profiling to characterize the expression of groups of genes involved in specific functions (such as proliferation and apoptosis) has been used to subdivide patients into those with good prognosis and poor prognosis. Similar investigations have begun in canine lymphomas but have not yet been used to determine diagnosis or prognosis. Currently investigators have developed the tools to carry out large-scale analysis of chromosomal duplications and deletions using comparative genomic hybridization arrays (Thomas et al., 2003). One early finding from this work is that particular breeds may be predisposed to particular types of chromosomal changes, raising the possibility that such studies may ultimately be able to uncover the genetic basis for a predisposition to developing lymphoma (Modiano et al., 2005). Such information would have implications beyond veterinary medicine since few genes linked to a predisposition to human lymphoma have been discovered.

In spite of better characterization of canine lymphoid malignancies into distinct histologic or genetic subgroups, this information has yet to make a routine impact on the day-to-day treatment options presented to pet owners. Additional studies are needed to better define the clinical characteristics of patients in each subgroup so that more individualized treatment can be pursued.

Feline Gastrointestinal Lymphoma

KEITH P. RICHTER, *San Diego, California*

EPIDEMIOLOGY

Lymphoma is the most frequently diagnosed feline cancer and the most common gastrointestinal (GI) neoplasm in cats. There are several anatomic locations for lymphoma; the GI tract is the most common site, accounting for 32% to 72% of total cases. Discrepancies in the reported incidence of the various forms of lymphoma may be the result of the differences in classification schemes used, a change in incidence over time, differences in feline leukemia virus (FeLV) subtypes in various geographic areas, and a decreased incidence of non-GI forms since the introduction of an FeLV vaccine. An increase in the proportion of GI lymphomas over time is apparent by comparing incidences in the same institutions over different time periods. For example, in the New England area the proportion of GI lymphomas in cats increased from 8% in 1979 to 18% in 1983 and to 32% in 1996. Likewise, in the New York City area the proportion of GI lymphomas in cats increased from 27% in 1989 to 72% in 1995.

The association between FeLV and lymphoma in cats is well established. The incidence of FeLV antigenemia in cats with GI lymphoma ranges from 0% to 38%. However, such estimation of FeLV infection rate is significantly influenced by the method of testing. Underestimation of FeLV incidence with immunohistochemistry (IHC) versus polymerase chain reaction (PCR) has been suggested. In one study PCR testing detected FeLV viral nucleic acid sequences in up to 63% of cats with GI lymphoma, whereas only 38% of cats were positive by IHC (Jackson et al., 1993). Generally cats with leukemia or mediastinal lymphoma tend to be young and FeLV positive, whereas those with GI lymphoma typically are older and FeLV antigen negative. An association between lymphoma and feline immunodeficiency virus also has been proposed, especially when coinfecting with FeLV.

GROSS PATHOLOGIC FINDINGS

The gross appearance of feline GI lymphoma varies with the specific anatomic location. Many segments of the GI tract, including the liver, may be involved. There can be a focal mass or diffuse infiltration. In some cases, especially with low-grade lymphocytic lymphoma, the gross appearance may be normal. When a focal alimentary tract mass is present, there is usually transmural thickening with or without mucosal ulceration. Mural thickening is often eccentric, resulting in preservation of the lumen, although a functional obstruction may develop. This contrasts with

intestinal carcinoma, which often results in a mechanical obstruction from decreased luminal diameter, often appearing as a “napkin ring”. With diffuse infiltration the intestinal wall may be visibly and/or palpably thickened. Mesenteric lymphadenopathy is often obvious grossly or on ultrasonographic examination. Intussusception can develop secondary to intestinal lymphoma, with the jejunum being the most common location. Hepatic involvement can have a variable appearance. In some cases the liver appears to be grossly normal, whereas in others there may be an enhanced lobular pattern, a mottled appearance, or a gross nodular appearance.

In summary, the appearance of lymphoma is extremely variable in all regions of the GI tract. In light of how commonly this neoplasm develops in cats, lymphoma should be considered as a differential diagnosis for GI illness with normal or grossly abnormal organ appearance.

HISTOPATHOLOGY AND IMMUNOHISTOCHEMISTRY

There are different grades of GI lymphoma, commonly referred to as low grade (lymphocytic or small cell), high grade (lymphoblastic, immunoblastic, or large cell), and intermediate grade. Less common descriptions such as large granular lymphocytic lymphoma also exist. Most published reports are either of undetermined grade or predominately high-grade lymphomas, although low-grade lymphocytic lymphoma was described in a large case series (Fondacaro et al., 1999). In this study 50 of 67 cats (75%) diagnosed with GI lymphomas had low-grade lymphocytic lymphoma. Criteria used to classify lymphoma as lymphocytic have been described (Fondacaro et al., 1999). In marked contrast to palpable masses of lymphoblastic lymphoma, masses formed by lymphocytic lymphoma are not distinct microscopically because the mucosa beyond the apparent mass is also involved.

The use of a standard grading scheme for GI lymphoma may lead to a greater recognition of low-grade lymphocytic lymphoma. However, criteria have been difficult to establish because of the difficulty in interpreting small endoscopic biopsies, differences in pathologists’ opinions, and a lack of characterization using IHC. Consequently further studies are needed to define specific criteria for differentiating lymphocytic lymphoma, lymphocytic inflammation, and T-cell infiltrative disease and to correlate such classifications with clinical outcome.

In addition, the role of endoscopic biopsies versus full-thickness biopsies needs to be better defined. Many pathologists are comfortable making the diagnosis on endoscopic biopsy analysis, whereas others believe that full-thickness biopsies are necessary. In my practice I rely heavily on the analyses of endoscopic biopsies. Although it is customary to consider that there is a continuum from inflammatory bowel disease to lymphoma, there are little supporting data.

Recently IHC has been used to better characterize feline lymphoma. In some studies GI lymphomas were more likely to be of B cell rather than T cell phenotype, whereas other studies describe a predominantly T cell phenotype. Furthermore, in a limited number of studies immunophenotype did not appear to correlate with response to chemotherapy treatment or survival. Thus further study is necessary to determine the clinical value of immunophenotyping.

CLINICAL FINDINGS

Signalment

Males appear to be predisposed to GI lymphoma. Although a breed predilection is not apparent, most cats are domestic shorthair. The median age ranges from 9 to 13 years in different studies, with an age range spanning from 1 to 18 years.

Clinical Signs and Physical Examination Findings

Irrespective of the histologic grade, clinical signs include weight loss, anorexia, vomiting, diarrhea, lethargy, and polydipsia/polyuria. Importantly, many cats have minimal or no vomiting and/or diarrhea, with anorexia, weight loss, or both as the only historical findings. Therefore, when confronted with these signs in a geriatric cat with an otherwise unrewarding initial evaluation, GI lymphoma should be considered as a differential diagnosis. Physical findings may include poor body condition, thickened intestinal loops, and/or a palpable abdominal mass. The presence of an abdominal mass is more suggestive of high-grade lymphoma. Notably many cats may have a normal abdominal palpation.

Ancillary Test Findings

Laboratory findings generally are noncontributory, with mild anemia and/or hypoalbuminemia most commonly seen. Abnormalities on plain abdominal and thoracic radiographs are also uncommon and usually nonspecific. An abdominal ultrasound examination may be helpful in many cases and is considered more sensitive than radiography. Lesions can be nodular (focal or multifocal) or diffuse. Although the most common ultrasonographic abnormality observed is thickening of the gastric or intestinal wall, other important findings include loss of normal intestinal wall layering, localized mass effects associated with the intestine, decreased intestinal wall echogenicity, regional hypomotility, regional lymphadenopathy, and rarely ascites. Since ultrasonography provides informa-

tion about the specific site of involvement of the lesion, as well as other abdominal organs, it assists in staging the regional extent of disease and in screening for concurrent disorders. It also allows for precise guidance of fine-needle aspiration or biopsy for cytologic or histopathologic sampling, and it can be used to noninvasively and objectively assess response to therapy. A limitation of ultrasonography would be the difficulty in assessing the exact anatomic location and extent of certain lesions, possibly because of the inability of ultrasound waves to penetrate gas-filled structures such as the bowel and lack of distinct fixed anatomic landmarks. Furthermore ultrasonography is very operator, experience, and ultrasound-system dependent. Findings may also be normal, especially in cases of low-grade lymphoma.

Endoscopy can be an effective tool for diagnosing GI mucosal lymphoma when involved areas are within reach of an endoscope. Most gross endoscopic findings are nonspecific, with considerable overlap with inflammatory bowel disease and other GI diseases. In many cases the endoscopic appearance can be grossly normal.

TREATMENT

Reports of treatment strategies for feline GI lymphoma are fairly limited, and only a few of these reports give detailed results in cats specifically with GI lymphoma. In addition, the outcome in different forms of GI lymphoma remains ill-defined because many reports do not describe histologic grade or results of complete anatomic staging and different combinations of chemotherapeutic agents were used.

A summary of reported treatments and outcomes in cats with GI lymphoma is provided in Table 73-1. In general, response rates are in the 50% to 67% range, with reported median survival times (MSTs) of 3 to 9 months. Few studies have evaluated outcome by histologic grade; however, those evaluating high-grade lymphomas only generally report poor outcomes (Mahoney et al. 1995; Fondacaro et al., 1999).

These findings contrast with those of cats having low-grade lymphoma. Fondacaro and associates (1999) described 50 cats with low-grade GI lymphoma, 36 of which were treated with chemotherapy. Twenty-nine cats with lymphocytic lymphoma were treated with prednisone (10mg/cat PO q24h) and high-dose pulse chlorambucil (Leukeran, Glaxo SmithKline; 15mg/m² of body surface area PO q24h for 4 days, repeated every 3 weeks). Sixty-nine percent of the cats achieved a clinical complete remission (CR), with a median disease-free interval for cats that achieved a CR of 20.5 months (range: 5.8 to 49 months). The MST for all cats was 17 months (range: 0.33 to 50 months), with an MST of 22.8 months for cats that achieved a CR (range: 10 to 50 months). Twelve of the 20 cats that achieved a CR were "rescued" with cyclophosphamide at a dosage of 225mg/m² of body surface area PO every three weeks. These cats had a cumulative median disease-free interval of 24 months (including first and second remissions) and an MST of 29 months (cumulative). Seven cats were alive at the time of data collection; all but one of these cats had received rescue treatment with cyclophosphamide. Adverse reactions

Table 73-1

Reported Outcomes Following Treatment for Cats With Gastrointestinal Lymphoma

Authors	No. of Cats (No. of GI Lymphoma Cases)	Protocol	% CR	Median ST	Comments
Cotter, 1983	7 (7)	COP	86	26 weeks	Grade not reported
Jeglum, Whereat, and Young, 1987	14 (14)	COP + M	NR	12 weeks	Grade not reported
Mooney et al., 1989	103 (28)	COP + M + LA	62	30 weeks if CR	Outcome in GI LSA not reported separately; grade not reported
Mauldin et al., 1995	132 (95)	COP + M + DOX + LA	67	30 weeks	Outcome in GI LSA not reported separately but location did not affect outcome; grade not reported
Zwahlen et al., 1998	21 (21)	COP + M + DOX + LA	38	40 weeks (41.5 weeks if CR)	Grade not reported
Malik et al., 2001	60 (14)	COP + M + DOX + LA	80	17 weeks (27 weeks if CR)	Outcome in GI LSA not reported separately; grade not reported
Kristal et al., 2001	19 (7)	DOX	26	12 weeks (64 weeks if CR)	Outcome in GI LSA not reported separately; grade not reported
Mahoney et al., 1995	28 (28)	COP	32	7 weeks (30 weeks DFI if CR)	25 High grade; 3 low grade
Fondacaro et al., 1999	11 (11)	COP or COP + DOX + LA	18	11 weeks	All high-grade
Fondacaro et al., 1999	29 (29)	Chlorambucil, prednisone	69	74 weeks (99 weeks if CR)	All low-grade

COP, Cyclophosphamide/vincristine/prednisone; CR, complete response; DFI, disease-free interval; DOX, doxorubicin; GI, gastrointestinal; LA, L-asparaginase; LSA, lymphosarcoma; M, methotrexate; NR, not reported; ST, survival time.

to chlorambucil were rare but included vomiting, diarrhea, anorexia, lethargy, and neutropenia. No cats required hospitalization or discontinuation of therapy. Subsequently neurologic side effects (including myoclonus and seizures) have been described in cats receiving chlorambucil.

Some conclusions and recommendations can be made from these studies. In general, response to chemotherapy for high-grade GI lymphoma is poor, whereas the clinical response for low-grade lymphoma is good. For cats with high-grade GI lymphoma, combining doxorubicin with other agents in a multiagent protocol such as cyclophosphamide/Oncovin (vincristine)/prednisone (COP) and L-asparaginase is associated with longer remission and survival times when compared with single-agent doxorubicin or COP alone. For cats with low-grade lymphoma, excellent results can be achieved with oral prednisone and high-dose pulse chlorambucil therapy. However, it is unknown whether these cats would do better with a more aggressive multiagent protocol or even with a low, every-other-day dose of chlorambucil. For example, some institutions use 1 mg of chlorambucil orally every other day. Finally, chemotherapy generally is well tolerated by cats. Self-limiting anorexia, vomiting, diarrhea, and myelosuppression may be observed in some patients. It may be difficult to distinguish some of these chemotherapy-related side effects from active or progressive lymphoma.

The role of surgery in the treatment of GI lymphoma has been evaluated. Studies have shown either no effect or a negative effect of surgical intervention on disease-free interval and survival. However, this effect is most likely not caused by the surgical intervention itself but is more likely because cats requiring surgery (i.e., those with GI obstruc-

tion) have shorter survival periods because of the severity of their disease. The main indications for surgery are partial or complete intestinal obstruction, intestinal perforation, or to obtain biopsy specimens for definitive diagnosis. It should be noted that some patients with solitary masses that are surgically resected and subsequently receive chemotherapy can have long survival times.

It is believed that some patients with transmural focal disease are at risk for perforation when treated with cytotoxic chemotherapy that induces a rapid response, although this is rare in my experience. Surgery may result in dehiscence at intestinal anastomosis sites and may require a delay in initiation of chemotherapy to allow proper wound healing. Following resection of a focal GI or mesenteric mass, chemotherapy is still warranted since most cases have diffuse or multifocal microscopic involvement, and lymphoma should be considered a systemic disease in most cases.

PROGNOSTIC FACTORS

Few prognostic factors have been defined for cats with GI lymphoma. Histologic grade is a strong indicator of outcome. Compared to cats with high-grade lymphoma treated with a multiagent chemotherapy regimen, cats with low-grade lymphoma treated with oral prednisone and chlorambucil have a significantly better remission rate and survival time. Therefore low- and high-grade GI lymphomas in many ways represent different disease entities and must be considered separately.

In a majority of studies the most significant prognostic indicator for a positive outcome is initial response to chemotherapy. In general cats that survive the initial

induction period and achieve remission generally also have a better long-term outcome. Although this may seem intuitively obvious, it may give clinicians and owners encouragement to continue chemotherapy treatment in cats that attain a CR. Otherwise there is no consistent association with any patient or tumor characteristic that is predictive of outcome (including sex, immunophenotype, clinical stage, age, and body weight). In most recent studies, FeLV virus antigenemia was not a negative prognostic factor. Some studies also showed little benefit of an exhaustive "staging evaluation" since very few factors have enough impact on prognosis to make their determination helpful. Investigators have looked at molecular markers as prognostic factors. However, argyrophilic nucleolar organizer region (AgNOR) frequency and proliferating cell nuclear antigen labeling index (PCNA-LI) showed no correlation with response to chemotherapy or survival (Rassnick et al., 1999; Vail et al., 1998). Similarly the immunophenotype of tumor cells also does not seem to correlate with outcome in cats. This is in contrast to dogs, in which a T cell phenotype has long been recognized as a negative prognostic factor for response to therapy and survival. Concentration of serum α_1 -acid glycoprotein, an acute-phase protein, has recently been evaluated in cats with lymphoma and was not shown to be useful in predicting response to treatment or survival. Limitations of many studies published include incomplete staging, inconsistent grading, multiple unsampled GI locations, lack of prospective randomization to different chemotherapy protocols, lack of control (untreated) patients, and lack of confirmation of remission through follow-up biopsies. Prospective, controlled, and randomized cohort studies with large numbers of cats aimed at investigating the response of each grade of GI lymphoma to uniform chemotherapeutic regimens seem warranted. Furthermore, additional studies to correlate clinical outcome with immunophenotype and molecular markers are needed.

CHAPTER 74

Paraneoplastic Hypercalcemia

DAVID M. VAIL, *Madison, Wisconsin*

Hypercalcemia of malignancy (HCM) is one of the most commonly recognized systemic manifestations of cancer (i.e., paraneoplastic syndrome) in veterinary and human medicine. The clinical recognition of HCM is important for several reasons: it may represent the first clinical sign of disease (presenting complaint); it may aid the search for distant or metastatic disease beyond the primary site; it may help quantify and monitor response to therapy; it may aid in the evaluation of recurrence; and its management may take precedence over treating the primary disease. These points combined with the ability of HCM to mimic other disease

conditions make a working knowledge of the diagnostic and management steps involved in HCM important.

TUMORS IMPLICATED IN HYPERCALCEMIA OF MALIGNANCY

Any tumor histotype can be associated with HCM; however, several are much more commonly implicated, including lymphoma (15% of all forms and nearly 40% of cranial mediastinal forms), apocrine gland (anal sac) adenocarcinomas, multiple myeloma, and feline head and neck squamous cell carcinoma. The mechanisms

by which these tumors result in HCM vary and will be considered subsequently. Although parathyroid adenomas can result in profound hypercalcemia, these tumors are often not included in a discussion of HCM because the cell of origin is normally involved in parathyroid hormone (PTH) production and the result is characterized as primary hyperparathyroidism (see Chapter 54).

CALCIUM HOMEOSTASIS

To understand both the mechanisms by which tumors can alter blood calcium levels and the means by which the clinician can intervene, knowledge of the normal calcium homeostatic machinery is necessary. Three organs, the gut, kidney, and bone, under the control of a complex set of hormones and cytokines are primarily responsible for serum calcium regulation. These three organs can exchange calcium across the extracellular fluid space; however, under normal conditions the net effect is a zero balance (Clines and Guise, 2005). Although several known (and unknown) humoral factors are involved in this complex interplay, PTH and vitamin D (in particular calcitriol, 1,25-(OH)₂D₃) are by far the most important. Calcitonin also receives attention for calcium homeostasis, but its actual role is poorly understood and likely limited to short-term regulation. Table 74-1 outlines the effects of these humoral regulators on their target organs. Systemic PTH concentrations are regulated primarily by serum calcium levels through a simple feedback loop involving calcium-sensing receptors on parathyroid cells. Renal hydroxylation of vitamin D to the most active 1,25-(OH)₂D₃ is regulated primarily through stimulation by PTH, hyperphosphatemia, and inhibition by calcitriol through a negative feedback loop via renal tubule receptors.

As our understanding of molecular cell signaling advances, it is becoming apparent that many of the aforementioned humoral factors involved in calcium homeostasis ultimately interact with these signaling pathways, which could serve as potential therapeutic targets and therefore are germane to the topic of HCM. The receptor

activator of nuclear factor-KB (RANK)/RANK ligand (RANKL)/osteoprotegerin (OPG) pathway is the most well-known PTH-signaling pathway controlling osteoclastogenesis. Briefly RANKL, largely under the control of PTH, leads to osteoclast activation, bone resorption, and hypercalcemia. OPG competes with RANKL for binding to RANK and has an opposite effect (i.e., counterregulatory to PTH).

ETIOLOGY OF HYPERCALCEMIA OF MALIGNANCY

Tumors typically produce hypercalcemia by one or a combination of two major mechanisms. The first and most common in veterinary oncology is indirectly through the production of systemically active humoral factors that unbalance normal calcium homeostasis. The second less common mechanism is secondary to direct effects on bone subsequent to tumor spread to bone by local extension or distant metastasis and the ensuing production of locally acting (and possibly systemically acting) mediators of bone resorption. In human patients, the second mechanism is actually the more common etiology because of the higher incidence of metastatic epithelial cancers (e.g., breast, prostate) in people. Regardless of which mechanism is most responsible, the calciotropic factors that unbalance normal calcium homeostasis in each case may be the same.

Parathyroid Hormone–Related Peptide (PTHrP)

The most commonly involved mediator of HCM is parathyroid hormone–related peptide (PTHrP). This protein, produced normally by a variety of cells, shares close sequence homology with PTH at the N-terminus and as such binds and activates the PTH receptor, resulting in similar but not identical effects as PTH. When it is produced at normal physiologic levels in the nontumor-bearing host, PTHrP has a wide variety of normal regulatory actions on several organ systems, including the skin, placenta, heart, bladder, and intestine. However, when

Table 74-1

Simplified Overview of Humoral Control of Calcium Homeostasis

Humoral Signal	ORGAN EFFECT				Net Effect
	Kidney	Gastrointestinal Tract	Bone	Parathyroid Gland	
PTH/PTH-rP	More Ca ⁺⁺ resorption	Indirectly more Ca ⁺⁺ absorption secondary to more vitamin D activation	More osteoclastic bone resorption		Increased serum Ca ⁺⁺
	Less PO ₄ ²⁻ resorption				Lower serum PO ₄ ²⁻
	More renal activation of vitamin D				
Vitamin D (1,25-(OH) ₂ D ₃)	Potentiates PTH mediated renal Ca ⁺⁺ resorption	More Ca ⁺⁺ absorption More PO ₄ ²⁻ absorption	More osteoclast bone resorption	Less PTH production	Increased serum Ca ⁺⁺ Increased serum PO ₄ ²⁻
Calcitonin			Rapidly less osteoclast bone resorption		Lower serum Ca ⁺⁺ Lower serum PO ₄ ²⁻

produced in supraphysiologic levels in HCM, PTHrP mediates hypercalcemia and has several significant progrowth, survival, and metastatic effects on the tumor itself. This is the primary mechanism by which apocrine gland adenocarcinoma of the anal sac in dogs produces HCM (Rosol et al., 1990, 1992).

Vitamin D (or Vitamin D Analogs)

Likely the second most important mediator of HCM is 1,25-(OH)₂D₃ or other active vitamin D analogs that can be produced directly by the tumor cells or indirectly by the renal parenchyma secondary to PTHrP elevations. This appears to be the most common etiology for HCM in human diffuse large cell non-Hodgkin's lymphoma. A significant percentage of dogs with lymphoma have also been shown to have high circulating levels of 1,25-(OH)₂D₃; and, although some may be secondary to increased production secondary to PTHrP expression (also occurring in a significant percentage of dogs with lymphoma), the concentrations present appear to support tumor-derived 1,25-(OH)₂D₃ production (Rosol et al., 1992; Meuten et al., 1983a, 1983b).

Other Potential Calciotropic Factors

Several other factors may be involved in HCM, either alone in limited cases or in combination with PTHrP or 1,25-(OH)₂D₃. These include PTH, interleukin-1 β (IL-1 β , formerly osteoclast-activating factor [OAF]), IL-6, prostaglandins of the E series, transforming growth factor- α (TGF- α), and tumor necrosis factor- α (TNF- α).

DIFFERENTIAL DIAGNOSIS FOR HYPERCALCEMIA

It is important to note that nearly half of elevated total calcium concentrations appearing on standard serum biochemistry profile reports are caused by laboratory error or interference secondary to hyperalbuminemia, lipemia, hemolysis, or acidosis. If the reported hypercalcemia does not fit the clinical picture, steps to confirm the value should be taken (i.e., with regard to hyperalbuminemia, performing an ionized calcium to confirm or using a simple mathematical correction for dogs):

$$\text{Corrected calcium} = [\text{Lab Ca}^{++} - \text{Albumin}] + 3.5$$

It should be emphasized that this "correction" is the "average" correction based on serum albumin and the 3.5 constant is the "best fit" relationship for dogs based on one study. The mathematical calculation based on albumin concentration is less accurate in confirming true hypercalcemia than the measured ionized Ca⁺⁺.

Beyond laboratory error, the differential diagnoses for hypercalcemia include HCM, primary hyperparathyroidism (parathyroid adenoma), hypoadrenocorticism, vitamin D toxicosis, renal secondary hyperparathyroidism, nutritional secondary hyperparathyroidism, granulomatous disease, and widespread bony disease. In addition, young growing animals may have a mild, transient hypercalcemia.

DIAGNOSTIC PLAN FOR HYPERCALCEMIA OF MALIGNANCY

The diagnostic plan for hypercalcemia of unknown origin should be performed, with consideration of the differential diagnoses, in a stepwise fashion, performing the most cost-effective and least invasive tests first. First diagnostic steps include performing a confirmatory ionized calcium, considering and "correcting" nonionized serum calcium for albumin if appropriate, and completing a careful complete physical examination (including rectal examination and lymph node palpation). Furthermore, a complete blood count, serum biochemistry profile, electrolytes, urinalysis, and tests of adrenal function should be obtained. In HCM secondary to PTHrP or primary hyperparathyroidism (parathyroid adenoma), serum phosphorous is typically low (unless significant renal disease is also present), whereas with vitamin D toxicosis serum phosphorous usually rises concurrently with serum calcium. The clinician must also be reminded that, in the face of hypercalcemia, renal concentrating ability is impaired because of interference with normal antidiuretic hormone function. Therefore isosthenuria and azotemia in the face of hypercalcemia should not be interpreted as being consistent with renal azotemia; rather prerenal azotemia is still very likely.

If the diagnosis is still uncertain at this point, the clinician begins a "tumor hunt," including aspiration of a few representative lymph nodes (even if they are of normal size), thoracic and abdominal radiographs, a bone marrow aspirate, and an abdominal/parathyroid ultrasound. Serum PTH and PTH-rP concentrations are also very helpful. In most cases of HCM resulting from a PTHrP-expressing tumor, PTHrP is detectable, whereas PTH is well below the normal range. Importantly, if the PTH concentration is in the normal range in the face of hypercalcemia, primary hyperparathyroidism (parathyroid adenoma) becomes the most likely possibility since nearly three fourths of these cases have PTH concentrations within the normal range (Feldman et al., 2005; see Chapter 54). In *cats* with elevated serum calcium the possibility of "idiopathic hypercalcemia" should be considered (Chapter 52) if other causes have been excluded.

In rare cases in which this thorough diagnostic approach still does not reveal the cause of hypercalcemia, surgical exploration of the parathyroid glands and/or the abdomen, or so-called *provocative testing*, may become necessary. Provocative testing makes the assumption that the hypercalcemia is caused by HCM secondary to either occult lymphoma or myeloma and involves a short course of chemotherapy (e.g., cyclophosphamide or vincristine) to see if the calcium levels normalize. If successful, then a full course of combination chemotherapy is instituted. It is important to note that corticosteroids should not be a part of the provocative protocol because they can lower, albeit modestly, serum calcium levels resulting from several non-HCM disease processes. A third option in animals with mild hypercalcemia that have mild clinical signs and are not azotemic is to pursue no therapy but to recheck the patient after 4 to 6 weeks. Occasionally an occult lymphoid neoplasm may become clinically apparent after this waiting period, or inconclusive test results may become more definitive with time.

CLINICAL CONSEQUENCES OF HYPERCALCEMIA OF MALIGNANCY

The severity of the observed clinical consequences of hypercalcemia varies with the degree and the rate of rise of serum calcium elevations. If the rise in serum calcium is slow and long-standing, the signs tend to be more subtle and nonspecific. Adverse effects include reversible and potentially irreversible renal effects, neuromuscular dysfunction (e.g., weakness, cardiac arrhythmias [QT shortening, bradycardia], GI hypertonicity, or constipation), anorexia, weight loss, nausea, and dehydration. Dehydration can lead to further declines in GFR and exacerbate the hypercalcemia. Most renal consequences of HCM are reversible and secondary to dehydration (i.e., prerenal azotemia); however, renal tubular calcification and necrosis can occur if the hypercalcemia is long-standing and marked. Weakness or nonresponsiveness secondary to the neuromuscular effects of hypercalcemia can progress to coma. In primary hyperparathyroidism (parathyroid adenoma), the most common clinical signs are attributable to urolithiasis or urinary tract infection (Feldman et al, 2005).

MANAGEMENT OF HYPERCALCEMIA OF MALIGNANCY

As with any paraneoplastic syndrome, the paramount goal should be removal of the inciting malignancy. Whether the initial therapy should be aimed at removing the tumor or at normalizing the calcium is based on the

severity of clinical signs attributable to hypercalcemia, the degree of renal impairment, and the ease by which remission of the primary tumor can be achieved. I find the algorithm presented in Fig. 74-1 to be helpful for creating a therapeutic plan. As stated previously, removal of the inciting tumor is ideal, and this may be relatively easy in the case of hematopoietic tumors such as lymphoma or multiple myeloma; however, if this is not possible initially (e.g., metastatic anal gland adenocarcinoma), therapies directed at lowering serum calcium should be instituted. Replacement of fluid deficits and diuresis with high sodium crystalloids (e.g., 0.9% NaCl), beginning at twice maintenance level volume expands the patient and promotes renal ionic exchange of Ca^{++} for Na^+ . It is important to monitor for signs of overhydration and semiquantitate urinary output in the event that hypercalcemic nephrosis is already present. Some also advocate the addition of the loop diuretic furosemide at this point to further enhance ionic exchange of Ca^{++} for Na^+ ; however, if given before volume expansion, this can result in further decline in glomerular filtration rate and can actually exacerbate the hypercalcemia. In addition, fluid diuresis alone is usually as effective; therefore I do not advocate the addition of furosemide. Other means of lowering serum calcium include the use of glucocorticoids, calcitonin, bisphosphonates, mithramycin, and gallium nitrate.

Glucocorticoids inhibit the action of vitamin D, counteract prostaglandins of the E series, decrease gastrointestinal uptake, and increase the urinary excretion of calcium. It is imperative that glucocorticoid use be reserved until a diagnosis has been confirmed for the cause of the HCM.

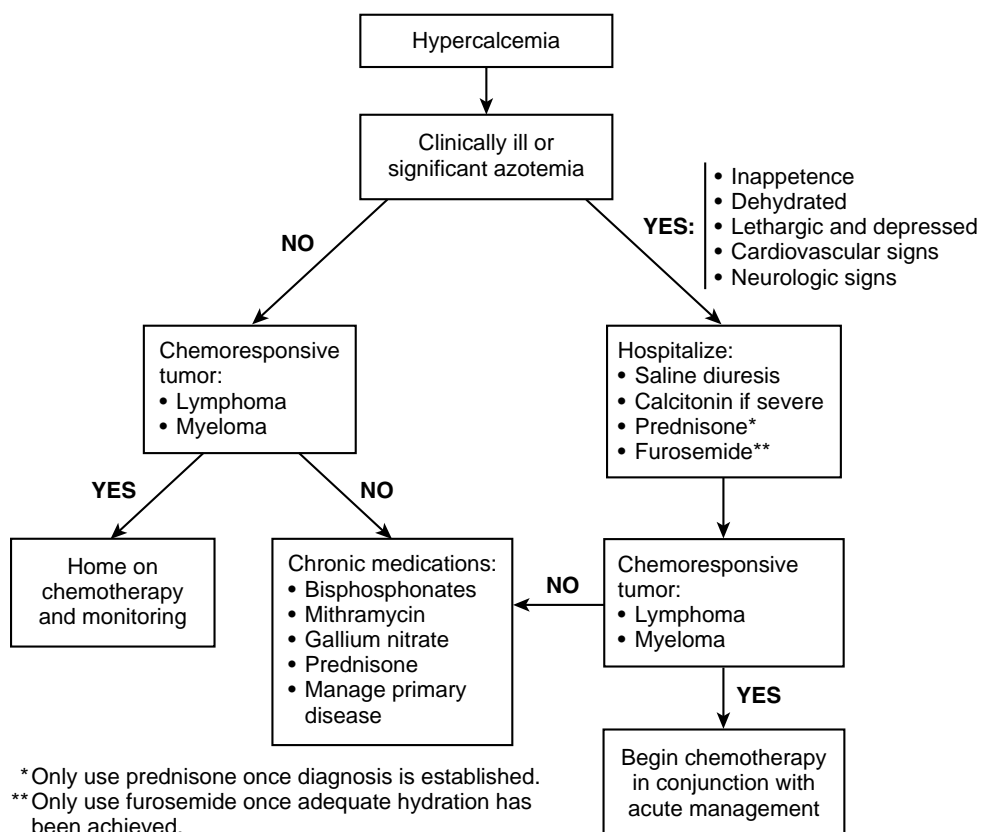

Fig. 74-1 Algorithm for management of hypercalcemia of malignancy.

Initiating glucocorticoids before diagnosis can result in short-lived remissions of lymphoma and myeloma, precluding a timely diagnosis and appropriate initiation of therapy. In addition, lymphoma that recrudesces following single-agent corticosteroid therapy can be less responsive to subsequent chemotherapy because of a selection for multidrug resistance.

Calcitonin is reserved for those cases in which the absolute serum concentration of calcium is extremely high and the clinical signs are marked (e.g., coma, cardiovascular emergency), necessitating intervention that will rapidly normalize serum calcium. Calcitonin (4 to 6 units/kg SQ BID) often normalizes serum calcium within 2 to 3 hours; however, “overshoot” hypocalcemia can occur, and the clinician should watch for signs of acute hypocalcemia (i.e., tremors, irritability, rubbing, and scratching at the face). Calcitonin is not for long-term use since tachyphylaxis (i.e., nonresponsiveness to subsequent treatments) can occur within a few days.

The bisphosphonate classes of drugs (e.g., pamidronate, zoledronate), although moderately expensive, have become the standard of care in human oncology for HCM and are rapidly becoming so in veterinary oncology (Clines and Guise, 2005; Fan et al., 2005; Hostutler et al., 2005; Milner et al., 2004; Pecherstorfer et al., 2003). They act by several mechanisms; however, the most important is to inhibit osteoclast function, thereby inhibiting normal and abnormal bone resorption. They do not act as quickly as calcitonin, taking a few days to normalize serum calcium; however, for long-term use they are superior. I use these agents primarily for cases in which the primary tumor is unlikely to be resolved and the patient is likely to experience long-term hypercalcemia (e.g., anal sac adenocarcinoma). Pamidronate has been used most frequently at a dose of 1 mg/kg in both dogs and cats (given intravenously along with 30 ml [cat] or 250 ml [dog] of normal saline as a 2-hour infusion), once every 4 to 6 weeks, to effect. The primary adverse effect of the bisphosphonates is renal tubular toxicity; thus appropriate hydration and periodic monitoring of renal parameters are important. A newer-generation bisphosphonate, zoledronate, has been used effectively in dogs (0.2 to 0.25 mg/kg in 200 ml of normal saline, infused intravenously over 30 minutes) with HCM. The calcium normalizing effects typically last approximately 4 to 6 weeks following a single dose (Fig. 74-2).

Mithramycin and gallium nitrate are mentioned more for historical importance, although the latter is enjoying a moderate resurgence in physician-based oncology in refractory cases and those cases with widespread metastatic disease.

INVESTIGATIONAL THERAPIES

The investigation of novel therapies for HCM is actively ongoing in human oncology because of the significance of the problem and the impact on quality of life for a large proportion of the tumor-bearing population (Clines and Guise, 2005). Disruption of the PTH-signaling pathway at the level of bone resorption (RANK/RANKL) through

Fig. 74-2 Serum calcium concentrations in a dog with hypercalcemia of malignancy secondary to an apocrine gland adenocarcinoma of the anal sac. At day 0 intravenous zoledronate at 0.2 mg/kg was given. Note that calcium decreased to normal by Day 8 and the effect was maintained for approximately 5 weeks.

the use of recombinant OPG or anti-RANKL antibodies is showing early promise. In addition, clinical trials evaluating anti-PTHrP antibodies are currently underway for women with metastatic breast cancer. Other potential targets to be modulated include the calciotropic factors involved in hypercalcemia, including IL-1 β , IL-6, TGF α , and TNF- α .

Histiocytic Disease Complex

PETER F. MOORE, *Davis, California*

VERENA K. AFFOLTER, *Davis, California*

HISTIOCYTIC DIFFERENTIATION AND CANINE HISTIOCYTOSIS

The development of canine-specific monoclonal antibodies for many of the functionally important molecules of macrophages and dendritic antigen-presenting cells (DCs) has enabled the identification of the cell lineages involved in canine and feline histiocytic disorders. Despite the large variation of clinical and pathologic features of histiocytic diseases, the majority represent proliferations of cells of various DC lineages.

Histiocytes differentiate from CD34+-committed stem cell precursors into *macrophages* and several DC lineages, which include *intraepithelial DCs* or *Langerhans cells* (LCs), *interstitial DCs* in many organs (e.g., dermal DCs in skin), and *interdigitating DCs* of T cell domains in peripheral lymphoid organs. DCs are the most potent *antigen-presenting cells* (APCs) for induction of immune responses in naïve T cells. Canine DCs occur in skin within the epidermis (LCs) and within the dermis, especially adjacent to postcapillary venules (interstitial DCs or dermal DCs). Canine DCs abundantly express CD1 molecules, which together with major histocompatibility complex (MHC) class I and MHC class II molecules are responsible for presentation of peptides, lipids, and glycolipids to T cells. Thus DCs are best defined by their abundant expression of molecules essential to their function as APCs. DCs also use adhesion molecules such as the $\beta 2$ integrins (CD11/CD18) in their function as APCs. CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is frequently expressed by DCs, whereas macrophages predominately express CD11b (or CD11d in the splenic red pulp and bone marrow).

Successful interaction of DCs and T cells in response to antigenic challenge also involves the orderly appearance of costimulatory molecules (B7 family—CD80 and CD86) on DCs and their ligands (CD28 and CTLA-4) on T cells. The defective interaction of DCs and T cells appears to contribute to the development of reactive histiocytic proliferative diseases, cutaneous histiocytosis (CH), and systemic histiocytosis (SH), which are related DC disorders arising out of disordered immune regulation (see following paragraphs).

Lineage distinctions among histiocytes (LCs, interstitial DCs, and macrophages) are best made via immunohistochemistry (IHC) performed on frozen sections with extensive panels of leukocyte markers (monoclonal antibodies). These analyses are only performed by specialized laboratories by prior arrangement since the fresh, unfixed biopsy specimen must be shipped overnight for optimum results. Less definitive but useful distinctions can also be

attained via IHC on routine formalin-fixed paraffin sections with panels of leukocyte markers developed for use in this format and more widely available in commercial and academic pathology services.

AN OVERVIEW OF CANINE HISTIOCYTIC DISEASES

Histiocytic disorders of dogs include histiocytoma and the related disorder LC histiocytosis (LCH), localized histiocytic sarcoma (HS), disseminated HS (malignant histiocytosis [MH]), and the reactive histiocytoses: CH and SH. These are a frustrating group of diseases because they may be difficult to differentiate from granulomatous inflammation, reactive inflammatory diseases, or lymphoproliferative diseases by examination of regular paraffin sections. The clinical presentation, behavior, and responsiveness to therapy vary tremendously among the syndromes. Clinical and pathologic images of canine histiocytic diseases and details of histiocytic lineages are available on a website that we maintain (<http://www.histiocytosis.ucdavis.edu>).

CANINE CUTANEOUS HISTIOCYTOMA COMPLEX

Histiocytoma

Histiocytoma is a common, benign, cutaneous neoplasm of the dog. Histiocytomas usually occur as solitary lesions that undergo spontaneous regression. The age-specific incidence rate for histiocytomas drops precipitously after 3 years, although histiocytomas do occur in dogs of all ages. Reports of local or distant recurrence of histiocytomas are rare, and multiple tumors are unusual. Epidermal invasion by cells of histiocytoma frequently occurs, and intraepidermal nests of histiocytes resemble Pautrier's aggregates, which are characteristically found in epidermotropic T cell lymphoma (mycosis fungoides [MF]). Epidermal invasion in histiocytoma, especially in aged dogs, can present a diagnostic dilemma; and distinction from MF is difficult on purely morphologic grounds.

Histiocytoma is readily distinguished from other histiocytic disorders and cutaneous lymphoma with the aid of IHC. Our work has shown clearly that histiocytomas have the phenotype of epidermal LCs; thus cutaneous histiocytoma is a localized epidermal LC tumor. Tumor histiocytes express CD1, MHC class II, CD11c, and E-cadherin. Among skin leukocytes, E-cadherin expression is unique to LCs. Histiocytomas lack expression of CD4 and Thy-1, which are consistently expressed by histiocytes

in CH and SH. Cutaneous T cell lymphomas are readily detected by the demonstration of CD3 expression.

Multiple Histiocytomas

Although rare, multiple histiocytomas occur more frequently in shar-peis. Multiple histiocytomas are also readily confused with CH on clinical appearance, although morphologically histiocytomas are consistently epidermotropic and commonly epidermally invasive, which are not features of CH. Delayed regression of multiple histiocytomas may occur, and lesions can persist for many months. We have a cohort of 35 dogs with multiple histiocytomas limited to skin; 11 dogs were shar-peis. Outcomes were available for 19 dogs; regression of histiocytomas occurred in 9 dogs. The remaining 10 dogs were euthanized, with survival times from days to 6 months. Another cohort of 12 dogs had multiple histiocytomas with concurrent lymphadenopathy caused by metastasis. Outcomes were available for 10 dogs; all were euthanized, with survival times from days to 9 months. Curiously, we have a cohort of four dogs with solitary histiocytomas, which metastasized to lymph nodes. Regression occurred in three dogs, and only one dog was euthanized.

Canine Langerhans Cell Histiocytosis

Canine LCH is a rare disease characterized by extensive regional cutaneous infiltration by histiocytes, which otherwise resemble those in histiocytoma, although rapid systemic metastasis is observed. LCH is also recognized as a rare disease of humans, in which marked variation in clinical behavior is recognized. We have a cohort of 11 dogs with LCH, occurring over an 11-year period. Outcomes were available for 10 dogs, which were all euthanized within days to 3 months.

Therapy

There is no effective medical treatment for LCH or the aggressive histiocytoma syndromes described in the previous paragraphs. Surgical management is indicated if the number of tumors allows. Treatment with corticosteroids or other immunosuppressive drugs (e.g., cyclosporine A) is contraindicated since regression of histiocytomas consistently occurs via activation of cytotoxic T cells, which would be inhibited by immunosuppression. Treatment with lomustine (chloroethylcyclohexylnitrosourea [CCNU]), which has been used widely in the treatment of HS, has not been successful. Radiation therapy may be efficacious but has not been widely used because of the extensive topographic involvement commonly encountered in these aggressive syndromes.

CANINE REACTIVE HISTIOCYTOSES

The reactive histiocytoses traditionally have included CH and SH. We believe that the continued distinction of SH and CH as entirely separate entities is probably no longer justifiable. It would be preferable to consider them within the spectrum of reactive histiocytoses of interstitial DC origin, in which clinical outcome is predictable more by

the distant migratory potential of the proliferating histiocytes beyond the skin. In this view CH and SH would be regarded as skin-limited and systemic interstitial DC proliferations, respectively. A wide range of clinical behavior is to be expected within each grouping, with SH usually exhibiting more aggressive disease. CH and SH should not be confused with malignant DC disorders (HS and MH), which can occur in the same locations. Cytologic and immunophenotypic differences can distinguish these diseases in most instances.

Systemic Histiocytosis

SH was originally recognized in related Bernese mountain dogs. SH is a generalized histiocytic proliferative disease with a marked tendency to involve skin, ocular, and nasal mucosae and peripheral lymph nodes. The disease predominantly affects young to middle-aged dogs (2 to 8 years). It has been observed in other breeds (e.g., Irish wolfhounds, basset hounds) less commonly. Clinical signs vary with the severity and extent of the disease and include anorexia, marked weight loss, stertorous respiration, and conjunctivitis with marked chemosis. Multiple cutaneous nodules may be distributed over the entire body but are especially prevalent on the scrotum, nasal apex, nasal planum, and eyelids. Ulceration of the skin overlying the nodules is common. Peripheral lymph nodes often are palpably enlarged. The disease course may be punctuated by remissions and relapses, which may occur spontaneously, especially early in the disease course. In severe disease lesions become persistent and do not respond to immunosuppressive doses of corticosteroids.

Cutaneous Histiocytosis

CH is a histiocytic proliferative disorder that primarily involves skin and subcutis and does not extend beyond the local draining lymph nodes. CH occurs in a number of breeds. Evidence of spread beyond the skin and draining lymph nodes would invoke the diagnosis of SH, a closely related disorder. Lymphadenopathy has not been emphasized in published reports and has only been documented in a small number of our cases. The lesions occur as multiple cutaneous and subcutaneous nodules up to 4 cm in diameter. Overlying skin ulceration is common. Lesions may disappear spontaneously or regress and appear at new sites simultaneously. Lesions commonly are found on the face, ears, nose, neck, trunk, extremities (including foot pads), perineum, and scrotum.

Histiocytes in CH and SH express markers expected of DCs such as CD1, C11c, and MHC II. However, the lack of consistent epidermotropism in SH and CH lesions and the expression of Thy-1 (expressed by dermal DC) and CD4 (a marker of DC activation) suggest that histiocytes in these diseases are activated interstitial type DCs rather than LCs. In skin dermal DCs are mostly of interstitial DC type. The clinical behavior and consistent clinical response to immunosuppressive therapy with agents capable of inhibiting T cell activation have reinforced the concept that SH and CH occur in the context of disordered immune regulation arising from defective interaction between DCs and T cells. The end result of this

dysregulated immune interaction is chronic proliferation of DCs and T cells. The initiation of the process is probably antigen driven, although studies to identify the nature of the antigens involved have been unrewarding. Thus it is important to perform tests to rule out infectious agents in the initial workup of a reactive histiocytosis case (culture and/or special stains for microorganisms in tissue).

Therapy

Lesions of CH and SH may wax and wane and even spontaneously resolve without treatment in the initial presentation. If lesions are not in sensitive sites and are not bothersome, it is worth waiting a few weeks to see if spontaneous resolution will occur. Some cases of CH respond well to immunosuppressive doses of corticosteroids, but the majority of CH and SH cases do not respond to corticosteroid treatment. SH in particular is a progressive disease that eventually requires continuous immunosuppression (for details see Chapter 55). The current therapeutic agent of choice for reactive histiocytoses is cyclosporine A coupled with ketoconazole to reduce the necessary dose of cyclosporine A. Leflunomide is also highly efficacious, but until recently it was prohibitively expensive for use in large dogs. The recent availability of generic leflunomide has lowered the cost significantly. Dogs on these potent immunosuppressive drugs are susceptible to infections. Risk of exposure to infectious agents should be minimized (e.g., avoidance of events in which many dogs are in attendance). Routine vaccinations should also be suspended while dogs are immunosuppressed.

HISTIOCYTIC SARCOMA COMPLEX

HS and the related disorder MH occur with greatest frequency in Bernese mountain dogs, rottweilers, flat-coated retrievers, golden retrievers, and sporadically in many other breeds. HS occurs as solitary lesions in spleen, lymph nodes, lung, bone marrow, skin and subcutis, brain, and periarticular tissue of large appendicular joints. HS can also occur as multiple lesions in single organs (especially spleen) and rapidly disseminate to involve multiple organs. Thus disseminated HS is difficult to distinguish from MH, which is a multisystem, rapidly progressive disease in which there is simultaneous involvement of multiple organs such as spleen, lymph nodes, lung, bone marrow, skin, and subcutis.

Clinical signs of HS/MH include anorexia, weight loss, and lethargy. Other signs depend on the organs involved and are a consequence of destructive mass formation. Accordingly pulmonary symptoms such as cough and dyspnea have been seen. Central nervous system involvement (primary or secondary) can lead to seizures, incoordination, and paralysis. Lameness is often observed in periarticular HS.

The clinical, clinicopathologic, and pathologic features of the distinctive *hemophagocytic HS* were the subjects of a recent publication (Moore, Affolter, and Vernau, 2006). This disease is frequently confused with immune-mediated hemolytic anemia/thrombocytopenia by clinicians and clinical pathologists despite negative Coombs' tests in all cases. Regenerative anemia and thrombocytopenia have been documented consistently in hemophagocytic

HS. Affected dogs also frequently demonstrate hypoalbuminemia and hypocholesterolemia. Histiocytes expand the splenic red pulp, which leads to diffuse splenomegaly. Simultaneous involvement of bone marrow is observed consistently. Extensive invasion of hepatic sinuses without mass formation occurs via the portal vein; this lesion is often missed by pathologists in the early stages. Hemophagocytic HS is associated with rapid demise (mean survival is about 7 weeks). Severe anemia and attendant coagulopathy complicates clinical management.

Histiocytes in HS/MH lesions express leukocyte surface molecules characteristic of DCs (CD1, CD11c and MHC II). The exact sublineages of DCs involved in HS/MH have not been determined in most instances. The most likely candidates include interdigitating DCs in lymphoid tissues and perivascular interstitial DCs in other involved tissues. Diffuse expression of E-cadherin, Thy-1, and CD4 has not been observed in HS or MH in skin or other sites; this together with cytomorphology assists in the distinction of HS/MH from histiocytoma and reactive histiocytosis (CH and SH). In hemophagocytic HS histiocytes express CD11d instead of CD11c, and MHC II. Expression of CD1 molecules is inconsistent. This phenotype is consistent with macrophage differentiation rather than DC differentiation, in which abundant expression of CD1 and CD11c is expected. This phenotype may explain the aggressive erythrophagocytosis, which is prevalent in this disease.

Immunophenotyping and careful morphologic assessment should also avoid confusion of HS and MH with the large cell form of T cell lymphoma (CD3+), pleomorphic large B cell lymphoma (CD20+, CD79a+), plasmacytoma (usually CD45+, CD45RA+, CD79a+), and poorly differentiated mast cell tumors (CD18+ variable, CD45+, CD45RA+, Tryptase+, c-kit+).

Therapy

Localized HS affecting skin and subcutis has been cured by early surgical excision, which in some instances apparently has been successfully supplemented by local radiation therapy. In the case of periarticular HS, which occurs in the subsynovial tissues of the extremities, amputation of the affected limb is required as a result of the inoperable nature of the primary lesion, which usually ensnares structures vital to limb function. It is important to establish absence of gross metastasis via thoracic radiographs, abdominal ultrasound, and regional lymph node aspiration cytology before embarking on limb amputation. Even despite due diligence, early undetected dissemination may have occurred, and the dog may develop widespread metastatic disease. *Disseminated HS* (including MH) is not readily treated surgically since even in the splenic form early metastasis to the liver has often occurred. Response to chemotherapy has been at best brief, and the disease progresses rapidly (weeks to months) to death or euthanasia. Lomustine is the chemotherapeutic agent most commonly used to treat HS. Response to lomustine reportedly is better if the tumor burden is low. Hemophagocytic HS has been treated by splenectomy followed by lomustine chemotherapy. The rationale for this approach is that the major tumor burden is within the spleen; hence splenec-

tomy is the most expeditious approach to reducing tumor burden before lomustine treatment. However, in the few cases we've followed the survival time was not clearly prolonged by this protocol. The dogs did well initially, but the existence of prior micrometastatic foci resulted in clinical disease progression.

FELINE HISTIOCYTIC DISEASES

Cats have a narrower range of histiocytic proliferative diseases than dogs. Clear feline equivalents of cutaneous histiocytoma and the reactive histiocytoses (CH and SH) have not been described. Cats are afflicted by the HS complex and present with many of the same clinical syndromes as in dogs, including hemophagocytic HS. However, the incidence is much lower. The most common histiocytic disorder of cats is feline progressive histiocytosis (FPH), which has no canine equivalent. Two previous reports of cutaneous histiocytoma in the cat were likely examples of FPH.

Feline Progressive Histiocytosis

FPH is a disease of adult cats (mean 8.8 years; range 2 to 17 years; n=30). Cats present with skin lesions, which are solitary or multiple nonpruritic, firm papules, nodules, and plaques. Lesions have a predilection for feet, legs, and face. Lesions consist of poorly circumscribed epitheliotropic and nonepitheliotropic histiocytic infiltrates of the superficial and deep dermis, with variable extension into the subcutis. The histiocytic population is relatively monomorphic and well differentiated early in the clinical course. With disease progression, cellular pleomorphism is more frequently encountered, and the lesions are then indistinguishable from HS. Histiocytes express CD1a, CD1c, CD18, and MHC class II molecules. This immunophenotype suggests an interstitial DC origin of these lesions. Coexpression of E-cadherin, a feature of cutaneous LCs, was only observed in three cats. FPH followed a progressive clinical course; however, the lesions were limited to the skin for an extended period of time (mean 13.4 months; range 1 to 36 months).

Extracutaneous involvement was documented in all cats that were euthanized and evaluated (7/15 cats). The etiology of FPH remains unknown. FPH is best considered an initially indolent cutaneous neoplasm, which is mostly slowly progressive and may spread beyond the skin in the terminal stage.

Therapy

Chemotherapy or immunosuppressive or immunomodulatory therapy was not successful in any of the cats. Agents used included vincristine and vinblastine (two cats), lomustine (two cats), L-asparaginase (one cat), corticosteroids (11 cats), cyclosporine A (one cat), leflunomide (one cat), interferon- γ (one cat), retinoids (one cat), and antibiotics (three cats). Surgical removal of the lesions was not successful largely because of the appearance of new lesions at distant sites in all cats (n=8).

Nasal Tumors

LISA J. FORREST, *Madison, Wisconsin*

PATHOLOGY AND CLINICAL PRESENTATION

Tumors of the nasal passage and paranasal sinuses in dogs account for approximately 1% to 2% of all canine neoplasms, with the majority being carcinoma (60%) and sarcoma (30%) histologies. Further breakdown of histology includes adenocarcinoma, squamous cell carcinoma, fibrosarcoma, chondrosarcoma, and osteosarcoma. Dolichocephalic breeds and dogs with exposure to indoor coal or kerosene heaters are at increased risk for development of nasal tumors. Most dogs presenting with nasal tumors are middle to older age, with reported median ages of 7.6 to 11.3 years. Nasal tumors generally are locally invasive and slow to metastasize but can metastasize to local lymph nodes (mandibular/retropharyngeal and less often to lung, abdominal organs, bone, and brain). Clinical signs in dogs with nasal tumors include nasal obstruction/respiratory stridor, sneezing, reverse sneezing, epistaxis, facial deformity, and exophthalmos. Initially signs may respond partially to antibiotics or antiinflammatory treatments because of the concurrent inflammation and secondary bacterial infection that is inevitably present. These tumors often are quite locally advanced when diagnosed, and occasionally patients can present with neurologic signs (seizures, altered mentation, behavior change) secondary to destruction of the cribriform plate and extension into the brain.

STAGING AND DIAGNOSIS

Imaging

Thoracic radiographs to evaluate for pulmonary metastases and as a general cardiac and geriatric evaluation should be obtained. Nasal radiographs can be used to image animals with nasal disease and should include the following:

1. Straight lateral to medial view
2. Open-mouth ventrodorsal maxillary view, angled 10 degrees rostral-caudal
3. Intraoral dorsoventral maxillary view
4. Frontal sinus view (rostral-caudal oblique)

However, cross-sectional imaging is preferred. Computed tomography (CT) is the most commonly used imaging modality for evaluating dogs and cats with nasal disease, but magnetic resonance imaging (MRI) is also used. Both imaging modalities have advantages and disadvantages in the imaging of nasal disease in cats and dogs. Bone destruction is easier to identify on CT (Fig. 76-1), and soft-tissue changes are better delineated on MRI. Generally MRI studies are more expensive, and imaging time is

longer than CT studies. Because computer-based radiation therapy (RT) plans are commonly generated using CT images, CT may be the preferred imaging modality if RT is contemplated.

Biopsy

Biopsy and histology of the nasal tumor are needed for definitive diagnosis. Before the biopsy procedure, additional evaluation should include complete blood count and blood chemistry along with a clotting profile. Fine-needle aspiration cytology of mandibular lymph nodes should also be performed as part of tumor staging. A transnostril biopsy technique using a closed suction technique, a bone curette, or cup-type biopsy forceps should be performed under general anesthesia to collect a sample. Whenever a transnostril biopsy technique is used, it is important to measure and mark the biopsy instrument so as to penetrate no farther than the distance from the tip of the nose to the medial canthus of the eye. This prevents penetration of the cribriform plate. Tumor tissue generally is white in color; mild-to-moderate hemorrhage is expected and usually subsides within a few minutes. Cytology of nasal swabs or expectorated material is rarely rewarding. Some large nasal tumors protrude into the nasopharynx and can be sampled using retrograde rhinoscopy. When obtaining biopsy samples with smaller endoscopic instruments, there is also a risk of sampling surrounding inflammation as opposed to the tumor.

TREATMENT AND PROGNOSIS

A variety of treatments for nasal tumors are reported in the literature, including RT, surgery, cryosurgery, chemotherapy, or a combination of these modalities. Unfortunately long-term survival for dogs with nasal tumors generally has been poor, with median survival times ranging from 5 to 23 months, depending on the treatment used. Generally surgery is considered ineffectual as a sole treatment modality.

At this time external-beam RT alone (see Chapter 67) or in combination with surgery or chemotherapy is the most effective treatment available, and the clinician is encouraged to speak with a radiation oncologist or oncologist with experience in managing nasal tumors. Because of the close proximity of the eyes to the nasal cavity, there is unavoidable acute and late toxicity of RT to ocular structures. Most dogs develop keratoconjunctivitis sicca (KSC) and cataracts in at least one eye. Dogs may also develop retinal hemorrhage and corneal ulcers. Chronic ocular toxicities are seen in approximately 45% of dogs. Lower-energy orthovoltage RT has been used alone and after surgical exenteration of the nasal tumor with reported

Fig. 76-1 Computed tomographic axial slice of a dog with a nasal tumor at the level of the eyes. Note the soft-tissue attenuating material (tumor) in both caudal nasal passages and the nasopharynx. Tumor destruction of the hard palate (white arrow) is seen as thinning of palatine bone.

survival times of 7.4 to 23 months, respectively. Currently megavoltage external-beam RT, delivered via linear accelerator or Cobalt machines, is commonly used to treat nasal tumors, with reported median survival times of 5.9 to 19 months. The course of treatment varies among institutions and practices; treatments can be delivered on a daily Monday-to-Friday schedule for 2 to 4 weeks or on a Monday, Wednesday, Friday schedule for 4 to 6 weeks.

Cisplatin and other chemotherapy agents have been used in some dogs with nasal tumors because of their radiosensitizing properties. A recent study of 51 dogs treated with external-beam RT in combination with slow-release cisplatin chemotherapy reported a median survival time of 15.8 months. Recently a small study of eight dogs receiving chemotherapy alone reported a good outcome using a protocol of alternating doses of doxorubicin, carboplatin, and oral piroxicam.

Use of an accelerated fractionated RT protocol (4.2Gy \times 10 fractions = 42Gy) results in similar median survival times of 14 to 19 months, compared to more conventional fractionation schemes. Surgical exenteration following accelerated RT increased overall survival to 47.7 months in a small study of 13 dogs. However, the dogs reported in this study had significant morbidity associated with surgery; 69% of dogs had rhinitis, 31% had osteomyelitis, and 2/10 had significant hemorrhage during surgery that required a transfusion. Attempts at increasing the RT dose to the tumor by using a boost technique (additional dose delivered to a smaller tumor volume) resulted in increased normal tissue morbidity and no improvement in tumor control. With current methods, increasing total tumor dose is impossible without increasing normal tissue toxicity.

Feline Tumors

Nasal lymphoma is the most common nasal tumor in the cat followed by carcinoma and least often sarcoma. Clinical signs in cats include nasal discharge, dyspnea, epistaxis, stertor, facial deformity, and anorexia. Nasal lymphoma often extends into the nasopharynx. Treatment approaches for cats with nasal lymphoma include external-beam RT alone, chemotherapy alone, or combination RT and chemotherapy. As with dogs, treatment of choice for nasal carcinoma and sarcomas is external-beam RT. Many cats with nasal lymphoma eventually will have systemic spread of disease, although long-term local disease control is often reported following local therapy alone.

FUTURE DIRECTIONS

There is clearly room for advancement in the treatment of tumors of the nasal and paranasal sinuses. Use of CT and MR imaging has improved the ability to accurately delineate the tumors. The use of three-dimensional computerized treatment plans has also increased the accuracy of the delivered RT dose. More and more radiation oncology centers are installing linear accelerators with multileaf collimators, allowing the radiation oncologist to shape the treatment beam to the tumor and avoid critical ocular tissues. A multileaf collimator and appropriate software allow intensity-modulated radiotherapy (IMRT) in which the treatment beam intensity and the treatment field shape can be conformed. Helical tomotherapy, which is image-guided IMRT, was used in a small trial of dogs in which the goal was to treat the nasal tumor and avoid ocular structures. None of the dogs has experienced significant ocular side effects, and all dogs are visual with no signs of KCS or other uncomfortable ocular toxicity. Tumor response in the trial is similar to that previously reported. These results would indicate that the future of treating canine nasal tumors lies with IMRT technology and early diagnosis when tumor burden is smaller.

Pulmonary Neoplasia

KEVIN A. HAHN, *Topeka, Kansas*
SANDRA M. AXIAK, *Dallas, Texas*

LUNG

Pathology and Natural Behavior

The incidence of primary lung tumors in the dog and cat is low. The majority of tumors are malignant, and the most frequently reported tumor type is adenocarcinoma in both the dog and cat. The average age at presentation is 9 to 10 years in dogs and 11 to 12 years in cats. There is no breed or sex predisposition and no proven etiology. Clinical signs tend to occur late in disease and vary at presentation. Often a chronic nonproductive cough is present; however, lung tumors may be diagnosed incidentally during radiography for another indication. Other signs are lethargy, dyspnea, weight loss, and tachypnea. Lameness is seen in cats with musculoskeletal metastasis (lung-digit syndrome seen with pulmonary adenocarcinoma, bronchial carcinoma, and squamous cell carcinoma), and in dogs with hypertrophic osteopathy (rare in the cat).

Diagnostic Approach

Thoracic radiographs are the most important diagnostic test. Common findings are soft-tissue density mass(es) (discrete or ill-defined); lobar consolidation; and diffuse interstitial, alveolar, peribronchial, or mixed patterns. The appearance of pulmonary neoplasia in cats can vary dramatically, ranging from solitary lesions that may be cavitated to diffuse mixed patterns of disease. Differential diagnoses for discrete soft-tissue opacity masses are abscess, hematoma, cyst, and granuloma; for other patterns they are pneumonia, metastasis, hemorrhage, edema, and fibrosis. Thoracic ultrasonography and cytologic examination of needle aspirates, pleural fluid, or bronchoalveolar lavage washes can aid in diagnosis. However, it is important to note that sensitivity of detecting neoplasia in pleural effusions is as low as 60% in both the dog and cat; thus biopsy may be required for definitive diagnosis (Hirshbeger et al, 1999). Computed tomography (CT) may be used to better determine the extent of disease before surgery if this information will alter the owner's decision with regard to treatment (Paoloni et al, 2006).

Treatment and Prognosis

Surgical removal is the treatment of choice for primary lung tumors. Reported median survival times following lung lobectomy are in the 10- to 13-month range. Positive prognostic indicators are: absence of clinical signs at presentation, solitary nodule, peripheral location, and less

than 5 cm in diameter. Negative prognostic indicators are lymph node involvement, more than one nodule, central location, greater than 5 cm in diameter, and high histologic grade (Hahn and McEntee, 1998; McNiel et al., 1997). Small case series of chemotherapy with vindesine/cisplatin or vinorelbine have been reported in dogs, with antitumor activity observed with both protocols (Melhaff et al., 1984; Poirier et al., 2004). Radiation therapy for solitary lung masses has not been reported in veterinary medicine. Hypertrophic osteopathy in dogs, if present, usually resolves after removal of the primary mass. There is no information regarding the efficacy of postoperative chemotherapy for dogs or cats with lung tumors.

PLEURAL SPACE

Pathology and Natural Behavior

Primary cancer of the pleura is called mesothelioma. Exposure to asbestos, especially amphibole fibers (long and thin), is considered a risk factor in humans. The mechanism by which it causes malignant transformation is unknown. Mesothelioma is highly metastatic and can invade the diaphragm and implant on abdominal structures. Neoplastic differentials include metastatic tumors of the pleural space, which in both dogs and cats most commonly occur from carcinomas. The most common clinical sign is respiratory distress caused by pleural effusion (pericardial effusion can also occur with mesothelioma of the pericardium). Reactive mesothelial cells may be interpreted as malignant mesotheliomas based on cytology. However, a true mesothelioma in veterinary medicine is rare.

Diagnostic Approach

Fluid collected from the pleural space can range in appearance from hemorrhagic to chylous. Fine-needle aspiration can be obtained with ultrasound guidance, but cytologic diagnosis of pleural disease is problematic. Reactive mesothelial cells can appear malignant; thus cytology of fluid does not usually give a definitive diagnosis. Diagnosis usually requires a biopsy of the pleura via thoracotomy or thoracoscopy. Differentials include tumor seeding from cardiac hemangiosarcoma (HSA), chemodectoma, or metastatic carcinoma. Imaging of the thoracic and abdominal cavities is indicated to rule out primary tumors.

Treatment and Prognosis

Prognosis is poor for primary mesothelioma or for disease metastatic to the pleura. Since no successful definitive

treatments have been reported, the goal of treatment is palliation of clinical signs. Intracavitary cisplatin has been described in six dogs to reduce pleural effusion of various causes. The survival of three dogs with pleural mesothelioma ranged from 129 to 410 days, and duration of response lasted 129 to 306 days (Moore, Kirk, and Cadona, 1991). Intracavitary mitoxantrone and carboplatin, with or without intravenous chemotherapy, has been described in 12 dogs, with a median survival time of 332 days (Charney et al., 2005). Intracavitary carboplatin has been reported in one cat with suspected mesothelioma, with reduction of pleural fluid and a survival time of 121 days (Sparkes et al., 2005). Systemic chemotherapy has not been effective in either dogs or cats. Cyto-reductive surgery may be used for larger masses before intracavitary therapy. Similar therapeutic approaches may be considered for animals with pleural carcinomatosis.

MEDIASTINUM

Pathology and Natural Behavior

The incidence of mediastinal masses is low in both dogs and cats. The two most common differentials for a mediastinal mass are thymoma and lymphoma (LSA). Branchial cyst, ectopic thyroid carcinoma, and chemodectoma can also occur but are less common. The mean age at presentation is 9 years in dogs and 10 years in cats. Benign mediastinal cysts are also recognized in cats, and carry a good prognosis with transthoracic needle drainage.

Thymomas originate from thymic epithelium and are infiltrated with lymphocytes (making differentiation from LSA difficult). It is the epithelial portion of the thymic tissue that is considered neoplastic. Benign thymomas are noninvasive and well encapsulated, whereas malignant thymomas are locally invasive and aggressive. Thymomas rarely metastasize.

LSA is considered a systemic disease in both dogs and cats. Cats presenting with mediastinal LSA usually are young (mean age of 2 years) and positive for feline leukemia virus (FeLV). Clinical signs for mediastinal masses include coughing, tachypnea, dyspnea, anterior caval syndrome, muscle weakness, or megaesophagus caused by myasthenia gravis (a paraneoplastic syndrome associated with thymoma).

Diagnostic Approach

History may include cough, respiratory distress, or signs of esophageal disease. Physical examination findings include pitting edema of the head, neck, or forelimbs if precaval (cranial vena caval) syndrome is present. Lung sounds may be decreased because of compression of lung lobes by the mass or associated pleural effusion. Infrequently, Horner's syndrome is identified from compression of ascending sympathetic nerves. Peripheral lymphadenopathy may be present in dogs with LSA. Hypercalcemia in association with mediastinal LSA is common, with a 25% to 50% incidence rate in dogs; but it has also been reported with thymomas and thus cannot be used to distinguish between the two diseases. Thoracic radiographs reveal a cranial mediastinal mass, pleural effusion, and/or megaesophagus (Fig. 77-1). Ultrasonography of the medi-

astinal mass may be instructive, and can help distinguish solid tumors from cysts (especially in older cats). Fine-needle aspiration and cytology of thymomas generally reveal mature lymphocytes and sometimes mast cells, whereas fine-needle aspiration of LSA often reveals lymphoblasts. These procedures are optimally guided by ultrasound or CT. However, obtaining a definitive diagnosis with cytology is often difficult, and a biopsy should be considered to distinguish between LSA and thymoma. A CT scan can provide information for staging and surgical removal of thymomas but cannot differentiate between tumor types.

Treatment and Prognosis

Surgical excision is the treatment of choice for thymomas and can be curative. Radiation therapy is used if surgical incision is incomplete or not possible. With radiation therapy alone for the treatment of thymomas in both

Fig. 77-1 Thoracic radiographs (left lateral) **(A)** and ventro-dorsal view **(B)** in an FeLV-positive cat with lymphoma, showing mild pleural effusion and large mediastinal mass. *FeLV*, Feline leukemia virus.

dogs and cats the response rate is 75%, and the median survival time is 248 days in dogs and 720 days in cats (Smith et al., 2001). The prognosis for surgically resected benign thymomas without myasthenia gravis is good, with an 83% 1-year survival reported in dogs and 2-year median survival reported in cats. Chemotherapy targeting the malignant (epithelial) component of thymoma has not been shown to be effective in dogs or cats.

Systemic combination chemotherapy is recommended for the treatment of mediastinal LSA, with radiation therapy if needed to alleviate clinical signs. With an aggressive chemotherapy protocol, median survival times range from 6 to 12 months for dogs and 6 to 9 months (if FeLV negative) or 3 to 6 months (if FeLV positive) for cats. See Chapter 72 for further discussion of LSA treatment.

HEART

Pathology and Natural Behavior

Primary myocardial tumors are rare in both dogs and cats. The majority of tumor types are malignant. The most common tumor type in dogs is HSA, with the German shepherd dog being predisposed (Chapters 70 and 181). In cats the most common primary heart tumor is LSA. Other differentials for both the dog and cat include aortic body tumor (chemodectoma), ectopic thyroid carcinoma, and rhabdomyosarcoma. Dogs and cats are middle-aged to older at presentation. Most cardiac masses are located intrapericardially (intracavitary heart masses are rare) and can cause pericardial effusion. Mesothelioma of the pericardium can also lead to pericardial effusion.

Clinical signs vary and depend on tumor location and invasiveness. Clinical signs are variable. In acute intrapericardial hemorrhage, signs can be acute with collapse and features of hypotension and cardiogenic shock. Chronic pericardial effusion generally leads to congestive heart failure with jugular venous distension, ascites, and often pleural effusion. Syncope may be caused by cardiac arrhythmias, heart failure, obstruction to venous return, or ventricular outflow obstruction. Respiratory distress may also develop from pleural effusion, pulmonary thromboembolism, or metastatic lung disease. Acute death from tumor rupture and blood loss can occur. Major differentials for these clinical signs are idiopathic pericardial effusion, pericarditis, cardiomyopathy, congestive heart failure, and valvular insufficiency.

Diagnostic Approach

Electrocardiographic (ECG) findings may correlate with the mass location or be secondary to myocardial ischemia or pericardial effusion. Possible abnormalities include low amplitude QRS complexes, electrical alternans, ST-segment changes, and cardiac arrhythmias. Thoracic radiographs may show a globoid-shaped heart (as a result of pericardial effusion), cardiomegaly, heart base mass, or pulmonary metastasis. However, the cardiac silhouette may be just modestly increased in size making recognition of pericardial effusion difficult. Cytology of pericardial fluid occasionally may help to distinguish between neoplastic and nonneoplastic causes, especially with LSA.

Echocardiography is the test of choice to identify and determine tumor location and size, as well as the presence of pericardial effusion.

Treatment and Prognosis

Medical treatment is aimed at palliating signs of heart failure and arrhythmias. Pericardiocentesis is the initial treatment of choice to stabilize patients with cardiac tamponade (see Chapter 181). Surgical resection of accessible masses can be successful (consult an experienced thoracic surgeon). Palliation of signs of pericardial effusion can also be achieved by a pericardial window or pericardiectomy.

However, prognosis depends largely on the tumor type. For example, the prognosis for atrial or pericardial HSA in both dogs and cats is poor (see Chapter 70). Although surgical excision of right atrial HSA is feasible and associated with a relatively low rate of complication, metastasis generally occurs rapidly, and postoperative chemotherapy is indicated. The prognosis for most primary cardiac tumors is poor, and in general they do not respond well to medical management. Conversely, long-term survival exceeding one year is not uncommon with aortic body tumors (chemodectoma) palliated by a large pericardial window is much better (see below). The outcomes with pericardial mesothelioma are quite variable, and some long-surviving cases have likely been misdiagnosed due to pronounced mesothelial reaction.

MAJOR VESSELS

Pathology and Natural Behavior

Tumors arising from the carotid or aortic body are most commonly chemodectomas (arising from the chemoreceptor organs). Chemoreceptor organs are part of the parasympathetic nervous system and initiate changes in blood pressure, respiration depth and rate, and heart rate. Chemodectomas are nonfunctional, and clinical signs are caused by space occupation and mechanical disturbances. These tumors are more common in the dog than in the cat. Other differentials for heart base masses include thymoma, HSA, ectopic thyroid carcinoma, abscess, and granuloma. Dogs are middle aged to older at presentation, with males being at a higher risk for developing aortic body tumors. Brachycephalic breeds are at a higher risk of developing chemodectomas; this is thought to be caused by chronic hypoxia. Clinical signs are those associated with right-sided heart failure (aortic body mass: dyspnea, arrhythmia, ascites, pericardial or pleural effusion, coughing, cyanosis) or space-occupying mass in the neck (carotid body mass, dyspnea, Horner's syndrome, laryngeal paralysis). Concurrent endocrine neoplasia (testicular, ovarian, thyroid, parathyroid, adrenal, pituitary, and pancreatic) is a common finding, with an incidence of up to 50% in dogs.

Diagnostic Approach

Thoracic radiographs often show dorsal deviation of the trachea, a mass at the base of the heart, and right-sided

heart enlargement. Metastasis can also be seen in some cases. ECG can be normal; or electrical alternans, low amplitude QRS complexes, or arrhythmias (premature ventricular contractions or ventricular tachycardia) may be seen. Abdominal radiographs and ultrasound can be performed to check for involvement of the liver, spleen, or lymph nodes and the presence of ascites. Echocardiography can identify a mass at the base of the heart and pericardial effusion and can also aid in the determination of surgical resectability. Chemodectomas do not exfoliate well; thus cytology of pericardial or pleural fluid usually is not helpful. Definitive diagnosis requires histopathology from surgery or necropsy.

Treatment and Prognosis

Early surgical excision is the treatment of choice. However, chemodectomas tend to be highly invasive and also have the moderate potential to metastasize. Pericardiectomy can be performed at the time of biopsy and has been shown to extend survival time (whether or not pericardial effusion is present). In dogs with aortic body tumors, those that have a pericardiectomy have a median survival time of 730 days, whereas those without a pericardectomy have a median survival time of 42 days (Ehrhart et al., 2002). Even when the mass is not respectable, pericardial windows may be beneficial to prevent accumulation of pericardial effusion. This treatment may often be accomplished using minimally invasive “mini”-thoracotomy approaches or thoroscopic methods.

Radiation therapy has not been well studied as an adjuvant therapy in dogs and cats, although chemodectoma is considered a radiation-sensitive neoplasm in humans. The prognosis for both dogs and cats is guarded because of the metastatic potential and locally aggressive nature. The median survival time for dogs after surgical resection is 25 months.

Osteosarcoma

NICOLE P. EHRHART, *Fort Collins, Colorado*

TIMOTHY M. FAN, *Urbana, Illinois*

Appendicular osteosarcoma (OSA) is the most common primary bone tumor diagnosed in dogs, accounting for ≈75% to 80% of focal, malignant bone lesions. Arising from malignantly transformed osteoblasts, OSA frequently develops within the metaphyseal regions of long bones. Similar to most neoplastic processes, OSA tends to affect middle-aged to older dogs (7 to 10 years); however, some reports demonstrate an additional incidence peak at 2 years of age. Unlike some tumor histologies that clearly demonstrate strong sex predilections, the incidence of OSA only subtly favors development in males, with a reported male-to-female ratio of 1.5:1. Specific breeds with large skeletal mass, including Saint Bernards, rottweilers, Great Danes, greyhounds, and Labrador retrievers, appear to be at increased risk for OSA development.

DIAGNOSIS

History and Physical Examination

The most common sites of OSA development include the distal radius, proximal humerus, and proximal tibia. Given these anatomic sites, dogs with appendicular OSA commonly present for acute-to-chronic lameness and limb swelling. Clinical signs of lameness are often temporally associated with perceived traumatic events such as running, jumping, or rough play with other dogs. In addition to varying degrees of lameness, dogs may also present with significant peritumoral soft-tissue swelling. Following the onset of lameness, some canine patients partially improve with symptomatic therapy, including rest, nonsteroidal antiinflammatory drugs, or other analgesics; however, recurrent and progressive bone pain refractory to conservative therapy is the most common clinical disease course. Subsequent to long-standing chronic pain, dogs with OSA may demonstrate significant discomfort of the affected limb even following minimal or light manipulation; these are clinical signs suggesting the establishment of hyperalgesia and allodynia.

Imaging Modalities

In dogs with OSA radiography remains an important and valuable diagnostic tool for determining the extent of disease. Given the biologic behavior of appendicular OSA, every canine patient should have radiographs of not only the primary tumor site but also the thoracic cavity. At presentation, radiographs of the primary lesion typically reveal bony proliferation and lysis in the metaphyseal region of long bones, whereas thoracic radiographs

demonstrate gross metastatic disease in fewer than 10% of dogs. Despite the low incidence of overt metastatic disease at diagnosis, it is well established that the vast majority (>90%) of canine patients affected by OSA eventually develop radiographically evident pulmonary metastatic disease. In addition to determining the extent of disease at diagnosis, thoracic radiographs can also provide valuable prognostic information since dogs with visible pulmonary metastases typically have considerably worse long-term outcomes than dogs radiographically free of pulmonary metastases at presentation.

Additional advanced imaging modalities may be appropriate for patients being considered for less conventional, yet extremely effective treatment options such as limb-spare surgeries. In such patients it is critical to ensure that additional skeletal metastases or metachronous primary lesions are not present before limb-spare procedures. For such global skeletal assessments the acquisition of whole-body radiographs is feasible; however, this methodology can be cumbersome and inefficient. Thus nuclear scintigraphy is the imaging modality of choice for assessing global skeletal health. Nuclear scintigraphy is more sensitive than plain radiographs for imaging skeletal metastases because it readily identifies alterations in bone remodeling dynamics, which develop before structural changes can be detected radiographically. Although scintigraphy to screen OSA patients for occult skeletal disease may be very sensitive, this methodology lacks specificity, and any scintigraphic “hot spot” should be verified by high-detail radiographs and subsequent biopsy.

DIFFERENTIAL DIAGNOSES

Differential diagnoses for OSA include other primary bone tumors, bacterial or fungal osteomyelitis, metastatic bone tumors, and systemic diseases that affect bone such as multiple myeloma or lymphoma. Benign processes such as bone cysts and degenerative or active remodeling can also be considered. It is important to obtain a complete history (including a travel history to areas of endemic mycotic infection) so that the clinician can take into account all factors when making a diagnosis. Radiographic appearance is helpful, especially when there is a classic appearance in a classic location. However, the classic radiographic appearance of OSA (metaphyseal location, mixed lytic and blastic pattern, loss of trabecular pattern, cortical lysis, Codman’s triangle, sunburst periosteal pattern, and soft-tissue swelling) is not present in every case. In addition, other primary bone tumors may have a similar radiographic appearance. Multiple affected bones are uncommon in OSA; however, synchronous

primary OSA occasionally can occur. Metastatic disease affecting bone is usually in a diaphyseal location rather than in the metaphysis but can be either lytic or proliferative. Multiple punched-out lesions in several bones suggest multiple myeloma.

The most accurate means to differentiate OSA from other bone diseases is through a bone biopsy. However, because bone biopsy is an invasive procedure and the results are not always immediately available, fine-needle aspiration cytology can be helpful initially to help rule out other differential diagnoses. Most bone tumors have a soft-tissue component that yields cells on needle aspirate. A cytologic specimen devoid of inflammation and yielding a population of malignant mesenchymal cells supports the diagnosis of a primary bone malignancy. OSA cannot be differentiated from chondrosarcoma, synovial cell sarcoma, and fibrosarcoma on a cytologic specimen with standard staining methods. Staining for alkaline phosphatase activity has been reported to be helpful to further characterize malignant mesenchymal cells as OSA from bone tumor aspirates. Presumably only mesenchymal cells of osteoblastic origin (OSA cells) should stain positive for alkaline phosphatase. In one study alkaline phosphatase staining of 61 bone lesion aspirates provided an accurate diagnosis of OSA with 100% sensitivity and 89% specificity (Barger et al., 2005)

The gold standard for diagnosis remains the biopsy. There are several methods for obtaining bone tissue for biopsy. The two most common techniques are either closed biopsy using a Jamshidi bone marrow biopsy needle (American Pharmaceutical Company) or open biopsy using a trephine or curette. Both methods require general anesthesia, and regional radiographs should be available to aid the clinician in selecting an appropriate area within the tumor to collect the biopsy. Attempts should be made to obtain a sample from the center of the radiographic lesion. Advantages of needle biopsy are that the procedure can be done through a single tiny stab incision without a surgical approach. The resulting bone defect is small, typically involving a single cortex, and therefore is unlikely to initiate a pathologic fracture. The disadvantage of the closed technique is the relatively small sample size obtained. An open biopsy using a trephine requires a surgical approach and creates a bigger defect through both cortices; however, the sample obtained is larger. A larger sample may provide more representative tissue, thereby allowing a more accurate diagnosis. The down side of this is that there is a higher potential risk for pathologic fracture. Regardless of the method used to obtain the biopsy, it is important to send the tissue to an experienced pathologist with expertise in bone pathology.

It must be emphasized to clients that no diagnostic test is 100% accurate. A diagnosis of reactive bone is not uncommon on preoperative biopsy of an OSA, whether obtained by needle core or trephine. In cases in which the histopathologic interpretation does not match the clinical picture, OSA should not be ruled out. A histologic report of reactive bone from a lesion with classic OSA appearance on radiographs may simply be a function of the fact that the relatively small sample was not representative of the true underlying pathology. In some

cases repeat larger biopsies still yield reactive bone; yet, when the entire lesion is submitted following definitive surgery, the pathologist can readily make a diagnosis of OSA. Similarly, one should be cautious when interpreting bone biopsy results indicating the presence of primary bone fibrosarcoma, chondrosarcoma, or hemangiosarcoma. Although these other primary tumors do occur on occasion, OSA is far more common. In fact, OSA has various histologic subtypes, including fibroblastic, chondroblastic, and telangiectatic (hemangiosarcoma-like), that can be interpreted incorrectly on small biopsy samples where there is little-to-no osteoid present.

BIOLOGIC BEHAVIOR

Appendicular OSA is a locally invasive, highly metastatic neoplasm. Although arising from the medullary canal, OSA is rapidly invasive, with most patients demonstrating significant cortical bone destruction early in the course of disease. Osteosarcoma typically possesses the cellular machinery required for successful metastasis. The pulmonary parenchyma is the most common metastatic site, whereas involvement of regional lymph nodes appears relatively uncommon. Pulmonary metastatic lesions usually appear as discrete soft-tissue nodules, and multiple lesions are common. Additional sites of metastases include bone, skin, and other extraskelatal sites. Supporting the observed clinical behavior of canine OSA, several studies have identified key proteins associated with tissue invasion, metastasis, and angiogenesis in spontaneously arising OSA samples.

CLIENT EDUCATION AND TREATMENT OPTIONS

There are many treatment options available for OSA. Treatment choices fall into two major categories based on the pet owner's goals: palliative-intent treatments or curative-intent treatments. Palliative-intent treatments have as their main goal the relief of symptoms associated with OSA. With palliative treatment it is accepted that the disease will continue to progress during treatment. Curative-intent treatments have as their main goal prolonged symptom-free survival or cure. Although a true cure occurs in less than 10% of canine patients with OSA, survival can be greatly increased with the use of curative-intent therapy. Owners need to have an accurate understanding of a given treatment goal, possible side effects, benefits, costs, and lifestyle changes expected with each category (palliative- or curative-intent) of treatment and each treatment within a category.

It is important to emphasize that there are no "right" or "wrong" treatments; rather there are simply choices that must be made based on current published information, known tumor biology, and the individual patient's circumstances and co-morbidities. Because OSA is an aggressive disease and can be considered to be systemic at the time of diagnosis, curative-intent therapy must be multimodal (including both local and systemic therapy) to improve survival. At minimum, curative-intent therapy involves surgical removal of the tumor by amputation or limb salvage surgery and adjuvant chemotherapy. If no

treatment is given, most owners seek euthanasia within 2 months after diagnosis.

Surgical Options

Amputation

Amputation remains the gold standard of surgical therapy for OSA. Amputation is by far the simplest, least expensive surgical solution with the fewest complications. In addition, for most common OSA locations, amputation affords generous bone and soft-tissue margins, making the risk of local recurrence very low, and requires no special surgical training to perform. Forequarter amputation (removal of the scapula en bloc with the limb) for forelimb tumors and disarticulation at the level of the coxofemoral joint for hind limb tumors is recommended. Removal of the scapula for forelimb amputations results in a cosmetic outcome superior to disarticulation at the scapulohumeral joint. In patients with hind limb OSA, disarticulation at the coxofemoral joint provides a larger margin of normal tissue between the tumor and the amputation site. OSA may invade locally along fascial planes, making amputation using a midfemoral or proximal femoral osteotomy risky, especially for tumors located in the distal femur or proximal tibia. For OSA located in the proximal femur, partial hemipelvectomy (acetabullectomy) is required to prevent local recurrence.

Function, cosmesis, and patient acceptance following amputation have been excellent even in very large- and giant-breed dogs. Although deciding to move forward with an amputation in a large- or giant-breed dog with OSA is often difficult for owners, most are satisfied with the functional outcome. It is important to point out that in many cases amputation provides an improved quality of life that would not have been possible otherwise. Keeping amputation patients comfortable during the immediate postoperative phase is very important for a rapid recovery. To this end, preemptive analgesia is recommended before surgery, and amputation patients should remain hospitalized on injectable pain medications for at least 15 to 24 hours following surgery to ensure comfort. If effective analgesia is administered, most dogs are ready for discharge the day after surgery. Oral analgesics can be administered by the owner at home for the next 5 to 7 days following discharge. Owners should be instructed to keep early postoperative amputees away from slippery surfaces unless they can provide support using a sling. Most dogs are able to go up stairs immediately following discharge yet have some apprehension and difficulty going down stairs. Weight control and controlled physical activity are important for long-term mobility. Many large-breed OSA patients have concurrent preexisting degenerative joint disease in other limbs that will require lifelong management for the best functional outcome.

Limb Salvage Surgery

Several alternatives to amputation are available to salvage the OSA-affected limb. Limb salvage is a more costly and complicated option than amputation, and there is no survival advantage associated with limb salvage per se. The only advantage of limb salvage is that the patient retains the affected limb. Some dogs with severe concurrent

arthritis or neurologic conditions are not able to ambulate on three limbs and therefore require limb salvage if curative-intent treatment is pursued. However, more commonly owners choose limb salvage because an amputation seems like a less desirable option. Disadvantages of limb salvage are that it is a more complex surgery to perform, often requires specialized training and equipment, involves dissection very near the tumor (and therefore is associated with a higher risk of local recurrence), and has a high complication rate. Limb salvage surgery involves removal of the portion of bone affected by the tumor along with a margin of normal bone. Candidates for limb salvage surgery should have no known metastatic disease, no serious intercurrent health issues other than the OSA, no pathologic fractures, and a tumor involving less than 50% of the length of the affected bone with a small soft-tissue component. The most suitable cases for limb salvage are those with tumors in the distal radius. Except for rare circumstances, limb salvage requires arthrodesis of an adjacent joint. Dogs with carpal arthrodeses have excellent function, but arthrodesis of high-motion joints such as the knee and shoulder results in poorer limb function. As a result, limb salvage for tumors near the stifle or shoulder typically is not recommended.

Methods of limb salvage include allograft reconstruction, metal endoprosthesis reconstruction, and bone transport osteogenesis (BTO). BTO is a method of creating new bone in a defect by distraction using an external fixator. Choice of procedure depends on surgeon experience, case selection, and owner preference. All limb salvage procedures require an experienced surgical team and intensive aftercare. The most common complications associated with allograft and metal endoprosthesis reconstruction are infection and hardware failure (screw failure or back-out). Interestingly there seems to be a survival advantage in canine OSA patients that develop infection. Several retrospective studies have confirmed this observation. Limb salvage patients with OSA that develop infection survive 1.5 to 2 times longer than limb salvage patients that do not develop infection. Infection may be associated with an immunomodulatory effect that results in longer survival, although this has not been proven. Most infections in limb salvage patients can be managed with lifelong antibiotic therapy; however, periodic flare-ups occur, and occasionally amputation is necessary. Infection has not been reported as a complication with BTO limb salvage; however, these patients must have a circular external fixator on the limb for an extended period (several months), and the owner must be comfortable with adjusting the frame multiple times daily to create distraction osteogenesis for several weeks after surgery. Not every owner or dog is a good candidate for BTO limb salvage, and the number of surgeons experienced with the technique and postoperative management is limited. Overall limb use is good in 80% of all limb salvage patients. Local recurrence rates are 10% to 20% and do not differ between techniques. Local recurrence does not automatically require amputation since revision surgeries can be performed. Local recurrence does not negatively impact overall survival or metastatic rates. Therefore limb salvage is a viable surgical alternative to amputation for curative-intent treatment of canine OSA.

Other Ablative Surgery

Osteosarcoma located in the pelvis, maxilla, mandible, or scapula is often amenable to ablative surgery. Scapulectomy, hemipelvectomy, maxillectomy, or mandibulectomy can be used to successfully treat OSA and obtain clean margins in many cases. Advanced imaging such as magnetic resonance imaging and computed tomography is often necessary to discern appropriate candidacy for these types of procedures. Owners should seek the services of a surgical oncologist or board-certified surgeon who has specific experience with advanced oncologic surgeries such as these. Function and cosmesis can be excellent following scapulectomy, hemipelvectomy, maxillectomy, or mandibulectomy.

Systemic Chemotherapy

The adjuvant use of systemic chemotherapy for extending the survival time of dogs diagnosed with appendicular OSA subsequent to limb amputation or limb-spare procedures has been firmly established and demonstrated by multiple studies. Although a definitive consensus exists for the added survival benefit that chemotherapy provides, there remains some controversy as to which anticancer agents, used alone or in combination, are most effective. A simple answer for this fundamental question does not exist because response to systemic chemotherapy is not solely dictated by the anticancer agent used but equally influenced by the tumor population being treated. Given the heterogeneity of most canine OSAs, very large prospective studies would be necessary to determine the superiority of one chemotherapeutic regimen over another. Until such massive prospective studies are conducted, information regarding effective adjuvant treatment options will have to be based on more limited sample populations. In general effective adjuvant chemotherapy protocols are based around doxorubicin, platinum-based chemotherapy drugs, or combinations of the two. Results from select studies are included in Table 78-1.

NEW DEVELOPMENTS

Survival times for dogs and humans with OSA undergoing standard surgery and chemotherapy have reached a

plateau over the last 10 to 20 years. The biologic behavior, metastatic pattern, and response to chemotherapy of canine OSA are remarkably similar to their human counterpart. Recognition of this fact has led to collaborative relationships between human and veterinary cancer researchers who study OSA. As new agents and therapies become available, clinical trials involving these novel treatments are taking place in many veterinary cancer centers, often at much reduced costs to owners. Several of these treatments show promise for the future for both dogs and humans. Immunotherapy, therapeutic radiopharmaceutical agents, and γ -knife radiation therapy are some of the active areas of research in veterinary cancer centers. Many of these trials have led to pivotal clinical trials in human medicine and are shaping the way both humans and dogs with OSA will be treated in the future. Veterinarians should contact the major veterinary cancer centers in their area for up-to-date trial availability for their clients who are seeking new therapies for their pets with OSA (see Chapter 63).

PALLIATIVE THERAPIES

Reported survival times for canine patients treated with palliative-intent therapy range from 3 to 10 months. As stated earlier, it remains paramount that pet owners fully understand that the intent of palliative treatment is to improve quality of life, not cure the disease process. As such palliative treatment options center around controlling cancer-induced bone pain, a debilitating consequence of malignant osteolysis.

Palliative radiation therapy is effective for the management of malignant bone pain and typically involves administering coarse fractions of 8 to 10 Gy of megavoltage irradiation in 2 to 4 consecutive weekly treatments. Palliative radiation therapy reportedly improves limb function and quality of life in the majority of patients treated (74% to 92%), providing clinical pain relief for several months in responding patients (Ramirez et al., 1999; Green, Adams, and Forrest, 2002). The concurrent administration of systemic chemotherapy along with palliative radiation therapy appears to enhance analgesic response rates and durations and should be recommended.

Table 78-1

Select Postoperative Chemotherapy Regimens for the Treatment of Canine Appendicular Osteosarcoma

Surgery and Chemotherapy Protocol	Investigators	Median Survival Time
DOX (30 mg/m ² day 1) + cDDP (60 mg/m ² day 21) × 2 doses	Mauldin et al., 1988	300 days
cDDP 70 mg/m ² q21d × 2 doses	Straw et al., 1991	262-282 days
cDDP 60 mg/m ² q21d × 1-6 doses	Berg et al., 1992	325 days
DOX 30 mg/m ² q2wks × 5 doses	Berg et al., 1995	366 days
Carbo 300 mg/m ² q21d × up to 4 doses	Bergman et al., 1996	321 days
cDDP (50 mg/m ² day 1) + DOX (15 mg/m ² day 2) × 4 doses	Chun et al., 2005	300 days
Carbo (175 mg/m ² day 1) + DOX (15 mg/m ² day 2) × 4 doses	Bailey et al., 2003	235 days
Alternating carbo (300 mg/m ²) + DOX (30 mg/m ²) every 21 days × 3 doses	Kent et al., 2004	227 days

cDD, Cisplatin; DOX, doxorubicin; carbo, carboplatin.

The systemic administration of a bone-seeking radio-nuclide called $^{153}\text{Samarium-EDTMP}$ has been described for appendicular OSA in dogs and provides pain relief in many treated patients. By delivering concentrated radiation doses to the site of active bone remodeling, $^{153}\text{Samarium-EDTMP}$ administration is capable of providing significant and meaningful palliation of bone pain in dogs suffering from appendicular OSA (Lattimer et al., 1990). The main toxicity is myelosuppression, which may continue for up to 4 weeks after therapy.

Stereotactic radiosurgery involves the precise delivery of a single large dose of radiation to a designated tumor target and has been used for the treatment of brain tumors, as well as canine appendicular OSA. The use of stereotactic radiosurgery in dogs with OSA can provide pain alleviation, long-term local tumor control, and improvement in limb function (Farese et al., 2004). Similar to palliative radiation therapy, combining systemic chemotherapy with stereotactic radiosurgery appears to enhance response rates and durations.

The pharmaceutical use of bisphosphonates is accepted for the treatment of neoplastic bone disorders in human cancer patients. At low concentrations bisphosphonates inhibit bone resorption without inhibiting the process of bone mineralization. This results in stabilization and even enhancement of bone mineral density. Bisphosphonates directly inhibit bone resorption by binding to hydroxyapatite crystals and inducing osteoclast apoptosis. In part, pain associated with bone cancers is a direct consequence of malignant bone resorption. Therefore inhibiting pathologic bone resorption with bisphosphonates theoretically would decrease the likelihood of pathologic fracture, as well as alleviate intense bone pain. Intravenous pamidronate for the management of osteolytic pain in dogs with appendicular OSA has recently been described (Fan et al., 2005). Treatment with pamidronate at a dosage of 1 mg/kg or 2 mg/kg administered as an intravenous infusion every 28 days resulted in a clinical response rate of 40%, with responding patients demonstrating increased bone mineral density.

TREATING METASTATIC DISEASE

Approximately 90% of dogs with OSA ultimately succumb to metastatic disease despite treatment. Pulmonary metastasis is the most common form of treatment failure, although metastasis to bone is being observed more and more frequently. Dogs with metastatic disease have a wide range of reported survival times. In a recent study dogs with metastatic disease to any anatomic site had a median survival of 76 days with a range of 0 to 1583 days (Boston et al., 2006). In another recent study dogs with metastasis to the regional lymph nodes had a median survival time of 59 days with a range of 19 to 365 days (Hillers et al., 2005). Given the negative impact on survival time

for dogs diagnosed with regional nodal involvement, lymph node status should be evaluated routinely in dogs with OSA.

In some cases surgical removal of pulmonary metastases can improve survival. This requires either thoracotomy or thoracoscopy. Case selection is critical. As a rule, candidates for pulmonary metastasectomy should: (1) have no evidence of tumor elsewhere; (2) be at least 300 days from initial diagnosis (indicating that their particular tumor is no more aggressive than the average OSA); (3) have fewer than three detectable pulmonary nodules; and (4) have slowly progressive disease (a greater than 30-day doubling time of nodules). In one study dogs that underwent metastasectomy that met these criteria had a median disease-free interval of 128 days (O'Brien et al., 1993). Computed tomography is more sensitive than standard three-view radiographs for detection of small metastatic lesions and is recommended before surgery to ensure candidacy for pulmonary metastasectomy. Measurable metastatic disease is often resistant to standard chemotherapy. Some institutions have anecdotally reported responses using a combination of low-dose cyclophosphamide, nonsteroidal antiinflammatory agents, and doxycycline given daily (metronomic therapy). This combination is theorized to inhibit angiogenesis, thereby slowing the growth of metastatic lesions. Its efficacy in a large number of patients with metastatic OSA has not yet been studied.

Mammary Cancer

CAROLYN J. HENRY, *Columbia, Missouri*

Mammary tumors are among the most commonly encountered neoplasms in dogs and cats, consistently reported as one of the top three tumors in both species. Compared to their human counterparts, dogs are three times more likely to develop mammary tumors. Despite steady improvement in the survival rates for women with breast cancer over the past 30 years, there have been relatively few advances in the treatment of canine and feline mammary tumors. Perhaps the greatest progress has been in the area of public education regarding measures to prevent tumor development in both species. It has long been established that spaying dogs before the age of 2½ years is protective against the development of mammary cancer, and recent work suggests that ovariectomy at a young age (<1 year) has a similar protective effect in cats. Beyond educating clients regarding the potential benefits of ovariectomy, practitioners should alert clients to the relative frequency of mammary cancer development and the need for early detection and appropriate case management. This chapter summarizes what is known regarding the natural behavior and prognosis associated with canine and feline mammary tumors and provides guidelines for case management in both species.

CANINE MAMMARY TUMORS

Incidence, Etiology, and Pathogenesis

The incidence of mammary tumor development in dogs is difficult to determine since many small or benign-appearing tumors may go untreated and thus unreported. However, a recent insurance population study of female dogs in Sweden reported 111 mammary tumor claims per 10,000 dog-years at risk. Prior reports indicated that the annual incidence of canine mammary tumors (CMTs) in the United States approximates 200 per 100,000 dogs at risk. Breeds reported to be at increased risk include English springer, Brittany, and cocker spaniels, toy and miniature poodles, English setters, pointers, German shepherds, Maltese, Yorkshire terriers, and dachshunds. Mammary tumors most commonly affect middle-aged (9 to 11 years) female dogs, with an increased incidence beginning at approximately 6 years of age. The influence of hormones on CMT development is supported by the early work showing that the risk of developing mammary tumors rises to 26% for dogs spayed after their second estrus, compared to 0.5% and 8% for dogs spayed before their first or second estrus, respectively (Schneider, Dorn, and Taylor, 1969). It is thought that sex steroid hormones have their primary effect on target cells during the early stages of mammary

carcinogenesis, thus accounting for the lack of protective effect with spaying beyond two estrous cycles. The use of products containing medroxyprogesterone acetate (progestin and estrogen combination) for the prevention of estrus or to treat pseudopregnancy has also been linked to an increased incidence of CMTs. Although primarily a disease of female dogs, approximately 1% of CMTs affect males and can be associated with hormonal abnormalities such as estrogen secretion by a Sertoli cell tumor. Other factors reportedly associated with an increased risk of CMT development include obesity at a young age and feeding homemade diets as opposed to commercial foods. Compared to controls, dogs with CMTs in one study had lower serum retinol concentrations. However, additional research is needed to elucidate the impact of retinol concentration and other dietary components on CMT development.

Clinical Presentation

Mammary tumors are often detected during routine wellness examinations in older female dogs or are discovered by conscientious owners. In over half of all cases of CMT, dogs present with more than one mammary mass; these may either be simultaneous primary masses or may reflect one primary lesion with regional extension or metastasis. Although some studies have suggested that the caudal mammary glands are the most commonly affected in the dog, other reports have not confirmed this. Either the axillary or inguinal lymph nodes may be palpably enlarged in dogs with nodal metastases, given the complex pattern of lymphatic drainage for canine mammary tissue. Of the five pairs of mammary glands in the dog (two cranial/thoracic, two abdominal, and one caudal/inguinal), the thoracic glands generally drain to the axillary or sternal nodes, the inguinal glands are drained by the inguinal nodes, and the two abdominal glands may drain to either site. The presence of lymph node enlargement, lymphedema, skin ulceration, and fixation to underlying tissue is a characteristic that suggests malignancy.

Inflammatory mammary carcinoma (IMC) is a unique clinical entity that warrants an altered approach to diagnosis and case management. This tumor type may be mistaken for mastitis since dogs classically present with warm, erythematous mammary tissue and associated lymphedema; ulceration and vesicles; and significant pain on any manipulation of the tissue. Alternatively the diagnosis of IMC may become apparent when wound dehiscence occurs secondary to what was anticipated to be a routine mammary mass excision (referred to as secondary IMC).

Diagnostics and Staging

The diagnosis of CMTs relies on histologic examination of incisional or excisional biopsy samples. It is vital to bear in mind that benign and malignant nodules may coexist in canine mammary tissue. Thus it is necessary to confirm the histologic diagnosis independently for each nodule rather than assume that one nodule is representative of all tumors present. Estimates vary in the literature, but a simple rule of thumb for CMTs is that approximately 50% are malignant and approximately 50% of the malignant tumors metastasize. Tumor types reported in the dog and their relative frequency are detailed in Table 79-1. Of these, sarcomas and IMCs are associated with the worst prognosis. Mixed malignant tumors and squamous cell carcinomas are also associated with poor survival times. Of the carcinomas, solid carcinomas are reported to have worse survival times than either tubular or papillary carcinomas. Carcinomas that warrant a better prognosis include carcinoma in situ and adenocarcinomas.

The original clinical staging for CMTs was based on a four-stage system developed by the World Health Organization (WHO) and reported in 1980 (Owen, 1980). Since that time a modified staging system has been reported and is described in Table 79-2, with the primary difference being the addition of a stage V for dogs with distant metastatic disease and the designation of a stage IV (rather than stage II or III) for those with nodal metastasis. Either staging system necessitates evaluation of regional lymph nodes and assessment of potential distant sites of metastasis, especially distant lymph nodes and lungs. Preoperative cytology of any palpable lymph nodes may aid in determining disease extent before surgery. Regardless of preoperative assessment, lymph node tissue removed at the time of surgery should be submitted for histologic examination. Although standard hematoxylin and eosin (H&E) staining of slides from nodal tissue permits accurate identification of micrometastasis in most cases, cytokeratin immunostaining using an antipancytokeratin antibody AE1/AE3 was reported to detect occult micrometastasis in 12 of 131 (9.2%) lymph nodes from dogs judged

Table 79-1

Frequency of Various Histologic Types of Mammary Tumors in Dogs

Tumor Type	Relative Frequency
Benign (51%)	
Fibroadenomas (benign mixed tumor)	45.5
Simple adenomas	5.0
Benign mesenchymal tumors	0.5
Malignant (49%)	
Solid carcinomas	16.9
Tubular adenocarcinomas	15.4
Papillary adenocarcinomas	8.6
Anaplastic carcinomas	4.0
Sarcomas	3.1
Carcinosarcoma (malignant mixed tumors)	1.0

Figures were obtained from an unselected series of 1625 canine mammary tumors submitted by general practitioners to the Department of Clinical Veterinary medicine, Cambridge, England, for diagnosis. Reproduced with permission from Bostock R: Neoplasia of the skin and mammary glands in dogs and cats. In Bonagura JD, editor: *Kirk's current veterinary therapy VI: small animal practice*, Philadelphia, Saunders, 1977, p. 493.

to have node-negative disease based on H&E results. The impact of micrometastatic disease on prognosis for CMTs is unknown at this time. Three-view thoracic radiographs are essential before surgery because pulmonary metastases warrant a poor prognosis and may dictate therapy decisions.

In addition to clinical staging, a histologic staging system is outlined in Table 79-3. In this system stages 0, I, and II are based on histologic assessment, whereas stage III is based on clinical assessment of distant metastasis. This system is not to be confused with the clinical staging systems proposed in Table 79-2. Although the histologic staging system is not universally applied in veterinary medicine, it is highlighted in this chapter based on its correlation with clinical outcome in a report of 232 dogs undergoing mastectomy for CMTs (Gilbertson et al., 1983).

Table 79-2
Comparison of the Original and Modified Staging Systems for the Classification of Canine Mammary Tumors

Stage	Original WHO Staging	Modified WHO Staging
I	T1 (<3 cm) N ₀ M ₀	T1 (<3 cm) N ₀ M ₀
II	≤T2 (<5 cm) N ₁ M ₀ (histologically positive node, but not fixed to underlying tissues)	T2 (3-5 cm) N ₀ M ₀
III	Any T3 or any with fixed nodal involvement	T3 (>5 cm) N ₀ M ₀
IV	Distant metastasis (any T, any N, M ₁)	Regional node metastasis (any T, N ₁ M ₀)
V	No stage V	Distant metastasis (any T, any N, M ₁)

TNM system: T, size of primary tumor; N, regional lymph node involvement; M, distant metastasis. For example, N₀ is without lymph node involvement, and N₁ is confirmed lymph node involvement. WHO, World Health Organization.

Table 79-3

Histologic Staging System for Canine Mammary Tumors

Stage	Features	Frequency of de Novo or Recurrent CMT 2 Years After Surgery
0	Tumor cells are limited to ductal tissue	25%
I	Tumor cells invade stromal tissue	72%
II	Vascular/lymphatic invasion and/or regional lymph node metastasis	95%
III	Systemic metastasis	Not reported; dogs with Stage III disease by definition have no disease-free interval

Gilbertson SR et al: Canine mammary epithelial neoplasms: biologic implications of morphologic characteristics assessed in 232 dogs, *Vet Pathol* 20:127, 1983.

Treatment**Surgery**

Surgery is the mainstay of therapy for most CMTs, with the exception of IMC (see following paragraphs). In their pivotal study published in 1985, MacEwen and associates demonstrated that type of surgery is not a major prognostic factor for CMTs, provided resection is complete as assessed by histologic examination. Thus they established the surgical standard of care for CMTs that remains in place to this day to include minimal but adequate tumor excision, usually via lumpectomy or partial mastectomy. This has been supported by more recent studies, as well (Chang et al., 2005). The issue of whether or not to perform ovariohysterectomy (OHE) at the time of mammary tumor excision has long been debated in the veterinary literature. Given the high rate of estrogen-positive tumors in dogs, it is reasonable to consider hormone ablation via OHE as an adjunctive therapy for treatment of CMT. However, early reports suggested that no benefit was derived from spaying dogs at the time of tumor excision. Data from two more recent studies suggest that there is a survival advantage for dogs that undergo OHE. In the first report, dogs undergoing OHE within 2 years before or at the time of CMT removal survived 45% longer than intact dogs or dogs spayed more than 2 years before CMT excision (Sorenmo, Shofer, and Goldschmidt, 2000). In a subsequent study dogs undergoing OHE were more likely to survive at least 2 years after surgery than dogs that remained intact. This was especially true for dogs with complex carcinomas (Chang et al., 2005). Although one may not know the underlying diagnosis (malignant versus benign) at the time of surgery, these two latter studies certainly support a recommendation for OHE as an adjunct to complete tumor excision when feasible if malignant CMT is suspected.

Chemotherapy

Chemotherapy has not been clearly documented to provide a survival advantage for dogs with CMT. However, based on responses in women with breast cancer, various chemotherapy agents, including paclitaxel, fluorouracil (5-FU), cyclophosphamide, doxorubicin, mitoxantrone, and carboplatin have been used for treatment of high-grade or metastatic mammary carcinoma in dogs. In one prospective study comparing outcome for eight dogs with

CMT treated with 5-FU (150mg/m² intravenously [IV]) and cyclophosphamide (100mg/m² IV) once weekly for 4 weeks to that of eight dogs treated with surgery alone, a significant improvement in survival was demonstrated for the dogs receiving chemotherapy. Dogs in the chemotherapy group had a median survival time of 24 months compared to 6 months for dogs in the surgery only group. A more recent prospective study of postoperative doxorubicin or docetaxel (n=12) versus surgery alone (n=19) for dogs with invasive mammary cancer failed to demonstrate a significant impact of chemotherapy on recurrence-free interval, time to metastasis, or overall survival. Additional randomized prospective studies are necessary to determine the role of chemotherapy in the clinical management of dogs with mammary cancer.

Radiation Therapy

Although it is an important component of breast cancer treatment in women, radiation therapy remains largely unexplored for the treatment of CMTs. Anecdotal reports of palliation for nonresectable lesions or for IMC serve as the only current evidence to support radiation therapy for CMTs. Given the efficacy of radiation therapy in women with breast cancer, further evaluation of this treatment modality for CMTs is warranted.

Hormonal Therapy
